ABSTRACT

Objectives There are a wide range of physiotherapy treatment options for people with lateral elbow tendinopathy (LET); however, previous studies have reported inconsistent approaches to treatment and a lack of evidence demonstrating clinical effectiveness. This study aimed to combine the best available research evidence with stakeholder perspectives to develop key components of an optimised physiotherapist-led treatment protocol for testing in a future randomised controlled trial (RCT).

Design Online consensus groups using nominal group technique (NGT), a systematic approach to building consensus using structured multistage meetings.

Setting UK National Health Service (NHS).

Participants 10 physiotherapists with special interest in LET, 2 physiotherapy service managers and 3 patients who had experienced LET.

Interventions Two consensus groups were conducted; the first meeting focused on agreeing the types of interventions to be included in the optimised treatment protocol; the second meeting focused on specific details of intervention delivery. Participants were sent an evidence summary of available treatments for LET prior to the first meeting. All treatment options were discussed before anonymous voting and ranking of priority. Consensus for inclusion of each treatment option was set at ≥70% based on OMERACT guidelines. Options with 30%–69% agreement were discussed again, and a second vote was held, allowing for a change of opinion.

Results The optimised physiotherapist-led treatment package included: advice and education, exercise therapy and orthotics. Specific components for each of these interventions were also agreed such as: condition-specific advice, health-promotion advice, exercise types, exercise into 'acceptable' levels of pain, exercise dosage and type of orthoses. Other treatment options including electrotherapy, acupuncture and manual therapy were excluded.

Conclusion An optimised physiotherapist-led treatment protocol for people with LET was successfully developed using an online NGT consensus approach. This intervention is now ready for testing in a future pilot/feasibility RCT to contribute much needed evidence about the treatment of LET.

Strengths and limitations of this study

- The best available research evidence and stakeholder opinion were combined to develop an optimised physiotherapist-led treatment protocol for people with lateral elbow tendinopathy.
- The intervention was designed for delivery within the UK NHS context and so may need to be adapted to suit other healthcare systems.
- The effectiveness of the optimised physiotherapist-led treatment protocol now needs to be tested in clinical practice.

Trial registration number This is the pre-cursor to the OPTimiseE Pilot and Feasibility Randomised Controlled Trial. Registration: <https://www.isrctn.com/ISRCTN64444585>

INTRODUCTION

Lateral elbow tendinopathy (LET), commonly known as tennis elbow, is a painful condition affecting the extensor tendons of the forearm. It is most prevalent in the middle-aged population and therefore can impact on the individual's ability to work.^{1–4} Point prevalence has been estimated at 1.1%–1.3% of the general population.³ For many, it is a condition that resolves over the course of a year, even without treatment, but up to a third of people develop persistent symptoms despite accessing healthcare.^{5–10}

There are no established treatment guidelines, although an Australian group of researchers has proffered an algorithm for diagnosis and treatment,¹⁰ and in the UK, the National Institute for Health and Care Excellence has published a clinical knowledge summary providing advice on management and recommending referral to a physiotherapist.¹¹ Physiotherapists offer a wide array of different treatments including advice,

exercise therapy, manual therapy, acupuncture, electrotherapies, orthotics and taping.^{12 13} This heterogeneity can be attributed to multiple factors such as variations in training, variations in healthcare funding and personal or patient preference. With wide variations in practice, which include provision of treatments lacking evidence of effectiveness, there is a need to establish an evidence-based, optimum physiotherapy treatment package, to ensure that patients receive the most appropriate treatment in order to improve clinical outcomes for LET. Indeed, even more consistently used treatments, such as exercise therapy, lack a consistent approach to delivery with no consensus on the types of exercise to include, dose of exercise to prescribe and whether exercise should provoke pain or be pain free.^{12–16}

Physiotherapy treatment packages are complex interventions involving a combination of verbal and non-verbal communication, patient education and delivery of therapeutic modalities. When designing complex interventions, the purpose should be clear and the intervention should be informed by evidence prior to pilot and feasibility testing.¹⁷ More recent guidance, from O’Cathain *et al*, encourages stakeholder involvement, including those that deliver the intervention and those that may benefit from it.¹⁸

This paper reports on the development of an optimised physiotherapy treatment protocol for treating people with LET, using a consensus approach that combined information from a previous synthesis of the best available evidence (see online supplemental file 1) with the perspectives of key stakeholders. The agreed treatment protocol will be assessed in a forthcoming pilot and feasibility trial to determine if it can be delivered in a large-scale randomised controlled trial (RCT).

METHOD

The study gained stakeholder consensus for an optimised LET treatment protocol using a nominal group technique (NGT), which is a method that is, by design, dynamic, iterative, creative and open to change. The NGT is usually conducted in face-to-face meetings, about 2 hours long.¹⁹ For topics that are broad, it is recommended that participants are sent information to read prior to the meeting as a means of pre-elicitation: to facilitate understanding of the NGT process, provide background information (such as a summary of the research evidence of efficacy for physiotherapy treatments for people with LET) and prompt early consideration of the task proposed.²⁰ During the meeting, an explanation of the task is then followed by a period of silent idea generation where participants note down their opinions related to the topic or question. These ideas are then shared with the group until no more ideas are forthcoming. There is opportunity to discuss these ideas to gain understanding of individual’s perspectives and clarify definitions, prior to an anonymous vote on whether to include each of the ideas in the final consensus. If voting outcomes are inconclusive,

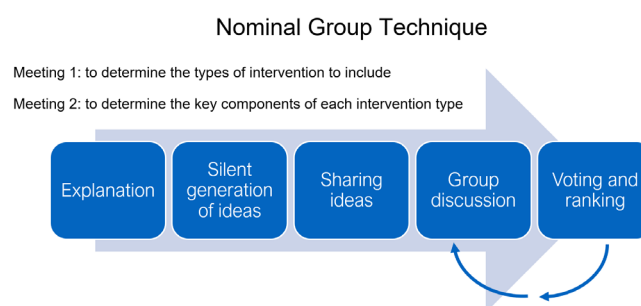

Figure 1 A summary of the nominal group technique process.

the process can be repeated with further discussion and voting until a conclusion is drawn.^{19 21} The process is summarised in figure 1.

Due to restrictions on face-to-face meeting during the COVID-19 pandemic, the NGT consensus approach was adapted for online data collection with meetings hosted on the Microsoft Teams video-conference platform. Physiotherapists with a special interest in LET were approached to take part via an email advertisement to members of the British Elbow and Shoulder Society and by direct contact with clinicians who had agreed to be part of recruitment and delivery sites for the subsequent pilot and feasibility RCT. Patients volunteered from an existing patient and public involvement and engagement group developed by the research team and physiotherapy service managers were identified from the future trial sites. All participants were required to give written consent to participate, including additional consent to meetings being video recorded.

Prior to the first meeting, participants were sent a summary of the evidence synthesis for the full range of LET physiotherapy treatments. The information was summarised in the form of an evidence flower—a visual display designed for conveying the best evidence summaries to professional and lay audiences (see figure 2).²² The quality assessment was taken from five previous systematic reviews, the majority of which used the Grading of Recommendations, Assessment, Development and Evaluations (GRADE) system of quality assessment.^{14 23–26} A narrative literature review was also included for those interested in further details about the evidence used (see online supplemental file 1). A comprehensive list of papers was included in the review using systematic search results from a concurrent project, supplemented by hand searching of paper references.²⁷ The purpose of the first meeting was to determine the broad types of treatment to include. During the first meeting participants were asked: ‘Which treatments should be included in the optimised physiotherapy treatment package for people with LET?’ They were also asked to consider the evidence presented in the summary documents, whether there were any other treatments that were not in the summary and if any treatments were not feasible for use in their specific UK NHS context. After silent generation of ideas and group

Figure 2 An evidence flower summary of the scientific evidence for the full range of physiotherapy treatments available for people with lateral elbow tendinopathy.

discussion, an anonymous vote was conducted using an online voting platform (www.mentimeter.com) with answers only revealed once everyone had voted. Participants were asked to signal ‘yes’ or ‘no’ for the inclusion of individual treatment types in the optimised physiotherapy treatment package. Ratings were averaged across the group, and those with $\geq 70\%$ agreement (based on the Outcome Measures in Rheumatoid Arthritis Clinical Trials (OMERACT) handbook)²⁸ were included. Those with less than 30% agreement were excluded. Treatment types with 30%–69% agreement were discussed further, followed by a second round of voting, to allow for changes of opinion, with those not reaching 70% agreement excluded after the second vote. Finally, the agreed treatment types were anonymously ranked by participants in order of importance using the Mentimeter online platform.

The purpose of the second NGT meeting was to reach consensus on the key components of the treatment types agreed in meeting 1. Prior to the second meeting, participants were sent a summary of the decisions made in the first meeting along with a two-page evidence summary of the component variables related to each of the treatment types selected (for example, the evidence of efficacy for different exercises to be included within the ‘exercise therapy’ treatment). Participants were also encouraged to read the more-detailed narrative literature review to gain a deeper understanding of the evidence available. The second meeting followed the same format as the first, with idea generation, discussion and voting on the individual components to be included within each of the treatment type categories.

Patient and public involvement statement

Patient representatives with experience of LET were involved in the initial study design, grant funding application and the consensus itself.

Figure 3 Results of the first voting round from meeting 1—to decide which treatment types will be included in the optimised physiotherapy treatment protocol. Overall, 10 votes were required for inclusion and 5–9 votes required for further discussion and a second vote. TENS, transcutaneous electrical nerve stimulation.

RESULTS

The consensus groups comprised 10 physiotherapists with special interest in LET (mean 18.7 years qualified, range 8–30), 2 NHS physiotherapy service managers and 3 patients (mean age 47). Two of the physiotherapists and one of the managers had also experienced LET themselves. There were eight male participants and seven females. One patient was unable to attend the first meeting due to illness, and all participants attended the second meeting.

The treatment types proposed and discussed in meeting 1 were: acupuncture, advice and education, exercise therapy, hyaluronic acid injection, laser, manual therapy, orthotics, shockwave therapy, steroid injection, taping, transcutaneous electrical nerve stimulation (TENS) and therapeutic ultrasound. Overall, 14 participants voted on whether to include these treatment types in the optimised physiotherapy treatment protocol, meaning 10 ‘yes’ votes were required to exceed the 70% threshold and 5 ‘yes’ votes required to exceed the 30% threshold. The voting results from the first round of voting are displayed in [figure 3](#). Advice and education, exercise therapy and orthotics surpassed the 70% threshold for inclusion. Manual therapy received 43% of the vote, so was discussed again. Following a second vote, the result remained the same (43%) so manual therapy was excluded. All other treatment types failed to reach the 30% threshold, so were excluded after the initial vote. The three included treatment types were then ranked in order of importance by anonymous vote, with the following outcomes:

1. Advice and education.
2. Exercise therapy.
3. Orthotics.

During the discussion stage of the NGT process, the recommendation from the physiotherapy service managers was that the intervention needed to be adaptable for online consultations, due to recent service changes resulting from the COVID-19 pandemic and

future uncertainties around face-to-face consultations in the longer term, and that numbers of follow-up sessions should be minimised to improve efficiency. Patients highlighted the importance of practicality, reducing burden on the patient, and were amenable to online consultation.

In meeting 2, the components of the advice and education treatment were proposed and voted upon. The voting results are shown in [table 1](#).

Sleep advice, diet advice, diabetes management and stress management advice failed to meet the 70% threshold but were discussed again and voted upon for a second time. During the discussion, it was agreed among participants that dietary supplements were listed as a separate option for the second vote alongside general diet advice. Following the second vote, only stress management advice and dietary supplements failed to reach the 70% threshold for inclusion, hence were excluded. The full list of agreed advice and education components was: what tennis elbow is, activity modification, pacing, promotion of self-efficacy, ergonomics for work or sport, medication advice, basic pain science, general exercise advice, smoking cessation, sleep advice, general diet advice and diabetes management. The ranking of these components in order of importance is displayed in [figure 4](#).

The components proposed and voted upon for the exercise therapy treatment were: forearm stretches, spine stretches, isometric loading, concentric loading, eccentric loading, shoulder girdle strengthening, shoulder girdle stability exercise and functional exercise. Spine stretches failed to meet the 30% threshold, so were excluded. Forearm stretches and shoulder girdle strengthening were discussed a second time. It was agreed that, on reflection, shoulder girdle strengthening and shoulder girdle stability exercises had significant overlap, so were merged into one category: shoulder girdle exercises. Both forearm stretches (80%) and shoulder girdle exercises (80%) reached the 70% inclusion threshold in a second vote, so the final agreed components were: forearm stretches, isometric loading, concentric loading, eccentric loading, shoulder girdle exercises and functional exercise.

Two further questions were then posed to the participants regarding key components of the exercise therapy intervention:

1. Should exercises provoke pain?
2. What dose of exercise should be used?

Following discussion and voting, it was agreed that exercise should provoke pain to a level that the individual patient deems acceptable to them. Forearm stretches should be held for 30s and repeated three times before and after loading exercises. Isometric exercises should be held for up to 60s and repeated five times, once daily. Concentric and eccentric loading should be performed in three sets of 10–15 repetitions, once daily.

For the orthotic treatment, three options were proposed: a counter-force elbow clasp, a wrist immobilisation splint and a tubular compression sleeve. Following

Table 1 Voting results from meeting 2, showing the key components of each treatment category.

| Component | Vote 1 | Vote 2 |

voting, the elbow clasp was included (80%) with the other two options excluded (7% and 13%, respectively).

DISCUSSION

An optimised physiotherapist-led treatment protocol for people with LET was successfully developed using an NGT consensus approach. The agreed intervention consists of (a) advice and education related to both the condition and wider health-related issues, (b) progressive exercise therapy and (c) the provision of an elbow clasp splint. Acupuncture, hyaluronic acid injection, laser therapy, manual therapy, shockwave therapy, corticosteroid injection, taping, TENS and therapeutic ultrasound were excluded.

The NGT consensus approach was easily adapted from the traditional face-to-face format to an online video-conference format without the need for any bespoke software. The online method had the advantage that participants did not have to travel to meetings, allowing for inclusion of a geographically diverse group. A potential disadvantage is that some potential participants could have been put off by the technical aspects of joining a meeting online or lacked the necessary devices, computer skills or internet connectivity.

This study involved a range of different stakeholders (ie, physiotherapists and physiotherapy service managers) that would be involved in future roll-out of the proposed intervention and also patients who would stand to benefit from it. It is hoped that this stakeholder involvement will make the agreed optimised physiotherapy treatment protocol deliverable in a real-life clinical situation. The decision-making process was largely influenced by the scientific evidence, with all of the physiotherapist stakeholders stating that they had read the full evidence review prior to the first meeting; however, the other stakeholders were influential, especially when the evidence was equivocal. Indeed, the input from the physiotherapy service managers shaped the intervention to ensure that all of the elements could be provided via remote online or telephone consultation, should the need arise. Following the result of the first vote in deciding the treatment types to be included, manual therapy was undecided and was

discussed again. Some clinicians argued in favour, due to the short-term pain relief that can be achieved with manual therapy, but both the managers and the patients argued against, due to the costs involved with delivering multiple sessions of manual therapy and the burden on the patient of having to attend frequently to receive it. As a result, manual therapy was excluded following a second vote.

The creative nature of the silent generation phase of the NGT process allowed for ideas regarding the advice and education components that differed from previous LET trials. Several trials have included patient education and advice, consisting of explanations of what LET was, reassurance, ergonomic advice, activity modification and medication advice.⁵⁻⁸ None, to date, have considered a more holistic approach to health that was reflected in our results, including advice regarding general exercise, smoking cessation, diet advice, sleep, diabetes management and pain science. This has the potential to improve a patient's overall health alongside influencing the outcome of their LET symptoms.

The components proposed for the exercise therapy intervention were largely in line with previous research evidence. An exception to this was stretching of the cervical and thoracic spine, proposed by four physiotherapists based on their clinical experience, in the absence of any research evidence, but this did not receive sufficient votes for inclusion or further discussion. Forearm stretches were a topic of debate after receiving 67% of the initial vote. Numerous studies have included forearm stretches as part of an exercise therapy intervention alongside strengthening exercises, making it impossible to assess the efficacy of the stretches alone. Only one, three-armed RCT of 94 patients, has compared forearm stretches against the addition of either eccentric strengthening or concentric strengthening.²⁹ Outcomes were measured at 6 weeks, with similar effectiveness across all groups. This evidence, along with testimony from two of the participating patients of the immediate pain-relieving effect of forearm stretches, resulted in a change of opinion for the second vote (80%) and inclusion in the exercise therapy treatment.

For the initial exercise therapy vote, shoulder girdle stability exercises had been proposed as well as shoulder girdle strengthening exercises. Following further discussion regarding the details of what participants understood/meant by the two different terms, this resulted in an agreement that there was overlap across the categories and that, overall, a more generic description 'shoulder girdle exercises' should be used and included in the exercise therapy treatment. This was largely based on evidence that people with LET have been found to have reduced strength of the shoulder girdle muscles compared with the contralateral arm.³⁰

It was agreed that the exercise therapy component should be a progressive regime including a range of exercises to suit patients at different stages of the condition or symptom severity. Previous studies had focused on a

single exercise type, for example, isometric loading, finding a plateauing of improvement over time, whereas combined regimes appeared more effective.^{8 31} By including a progressive regime, the aim was to avoid this plateau effect and allow patients to return to their normal level of function.

In a departure from the majority of previous LET studies, this consensus group voted unanimously to include exercises that provoke pain. With the exception of the Stasinopoulos protocol,³² which permits exercise into mild pain below 4/10 on a numerical rating scale, all other trials of exercise for people with LET have stated that exercises should be pain free. Pain-related fear can result in higher perceived pain levels due to stress, so an exercise approach that focusses on avoiding pain may exacerbate this response.³³ Features of sensitisation, such as this hyperalgesia, are a common feature in patients with LET, as identified by 10 studies included in a recent systematic review.³⁴ Pain-related fear was recognised as an important factor in this intervention development by all participants, as it could be a mediating variable in the effectiveness of the exercise therapy component. The initial vote was split (47:53%) as to whether to limit pain during exercise to the 4/10 level or let the patient decide how much pain was acceptable to them, but following further discussion influenced by the patient participants the final vote rested in favour of pain to a level that the patient deems acceptable (80%).

The choice of dose for the different exercise types included was largely justified on clinicians' experience and precedents from particular trials. A systematic review of different types of resistance exercises used to treat people with LET, from 2012, found heterogeneity in the dose of exercise prescribed, with no recommendation possible regarding the optimum dose.¹⁵ A subsequent systematic review, from 2020, focused just on studies of eccentric loading exercises and recommended that three sets of 10–15 exercises be performed daily, for a minimum of 6 weeks.¹⁴ This dose was agreed by the consensus group for both eccentric and concentric exercises. The dosing of forearm stretches and isometric exercises was chosen based on what the physiotherapists deemed most pragmatic and the patients deemed most practical/acceptable from examples taken from previous studies showing evidence of efficacy. The agreed dose for forearm stretches was a 30s stretch performed three times, before and after loading exercises (isometric/concentric or eccentric) as used in the Stasinopoulos protocol.³² The agreed dose for isometric exercises was maximal resistance, held for 60s and repeated five times, as used by Barratt and Selfe.³⁵ Two other dosing regimes were considered but the dose prescribed by Park *et al*,³⁶ of 50 repetitions of 10s holds, four times a day was considered too burdensome, and contractions based on percentage of maximum voluntary contraction from 20% increasing up to 35%, used by Vuvan *et al*,⁸ too complicated.

For the orthotic treatment, the decision was between a wrist immobilisation splint, a counter-force elbow clasp

and an elasticated elbow sleeve. The latter was proposed as a cheap alternative, but due to a lack of trial evidence to support its use was excluded with just 13% of the vote. The evidence would suggest similar levels of efficacy between wrist immobilisation splints and counter-force elbow clasps.^{37–39} The practicality of such devices was discussed with the counter-force elbow clasps the clear favourite (80%). Reasons given were that wrist immobiliser splints would easily become dirty or wet during work or daily tasks and that elbow clasps were simpler to provide and stock, as they are universal in terms of fitting the left or right arm and have fewer sizing options than wrist immobilisation splints.

The main strength of this study is that a clinical trial intervention protocol has been developed using the combination of the best available research evidence and stakeholder opinion. The optimised physiotherapist-led treatment protocol was designed to be deliverable in the UK NHS, but could be adapted to suit other healthcare systems. Other strengths were: the inclusion of multiple voting rounds to allow for discussion and change of opinion in light of new information and the use of the evidence synthesis to guide decisions based on the evidence base, which the study used a recommended consensus approach, and that voting thresholds were consistent with established OMERACT guidelines. A limitation is that it is based on evidence available at the time of the event and the opinions of those involved in the process. The decisions were largely based on scientific evidence but were influenced, particularly in cases where evidence was equivocal, by an individual's experience. It must also be noted that the effectiveness of the optimised physiotherapist-led treatment protocol still needs to be assessed against usual physiotherapy care before it can be recommended for use in a clinical setting. Funding and ethical approvals are in place to test this in a feasibility trial involving 50 participants.

CONCLUSION

This study successfully developed an optimised physiotherapist-led treatment protocol for people with LET, which was considered feasible by stakeholders and adaptable for use in online consultations, if required. It includes advice and education related to the condition and the patient's general health, progressive exercise therapy that provokes a pain response and the provision of an elbow orthosis. This intervention is now ready for testing in a future pilot RCT to contribute much needed evidence about the treatment of LET.

Initial Management Strategies

The NICE Clinical Knowledge Summary¹ suggests that initial management should recommend the use of analgesia such as paracetamol or topical non-steroidal anti-inflammatory drugs (NSAIDs), with a subsequent prescription of oral NSAIDs if ineffective. It is recommended to give advice to avoid heavy lifting, avoid forceful gripping and twisting activities, favour palm-up lifting rather than palm-down, and modify work by taking more rest breaks, alter work patterns and change practice regarding lifting.

Evidence for simple advice

Similar advice has been used as part of a wait-and-see control arm in five trials, along with simple reassurance that for the majority the symptoms of LET will settle over time.²⁻⁶ In all five, patients in the wait-and-see group improved with short-term patient-rated successful treatment ranging from 26.3% to 48% and longer-term success at one year ranging from 75% to 90%. It is unclear whether this represents the natural course of the condition or whether the advice improved outcomes, given that there have been no studies of advice versus a true wait-and-see approach.

Epidemiological studies suggest that there may also be a place for advice related to stopping smoking, improving diabetes control and promoting regular exercise two to three times per week based upon risk factors for developing the condition.^{7,8}

The Kings Fund, in 2015, set ten priorities for UK NHS commissioners that included self-management at number one, with the aim of promoting increased physical function and self-confidence.⁹ Self-management “refers to activities which promote health but also prevent deterioration by gaining skills which can be applied to new problems as they arise to increase self-efficacy in managing the condition as it progresses.”¹⁰ Systematic reviews of the musculoskeletal literature, whilst not specific to LET, show moderate to strong evidence for the use of exercise and psychological interventions, such as pain coping skills, as physical activity and pain catastrophising are strong mediators for outcome in studies of self-management.¹¹⁻¹³ It is recommended that self-management education is delivered to patients by healthcare clinicians and includes follow-up sessions rather than one-off advice, should include self-help materials, help patients to identify problems specific to themselves, assist the patient to form personalised coping strategies and enhance their self-efficacy by empowering them to take responsibility for their lifestyle choices.^{10,14,15} Applying such methods, in addition to the basic advice given in the LET trials previously mentioned, may further improve outcomes.

Sport-related advice

In racquet-sports players, it has been hypothesised that changing grip size on the racquet may help to reduce symptoms by altering the grip force required to hold it, but a laboratory study found no difference in muscle activity with different grip sizes.¹⁶ Racquet string tension has though been found to relate to changes in force transmission across the elbow during backhand tennis groundstrokes, with higher string tension resulting in higher force.¹⁷ Similarly, a tighter grip on the racquet combined with below-centre strikes on the racquet face result in higher eccentric wrist extension torque.¹⁸ Whilst these two studies were performed in laboratory experimental conditions, the biomechanical findings could be transferrable to real-world sport with advice to de-tension strings, grip the racquet less firmly and seek coaching to improve ball-strike technique.

Evidence for the use of analgesia

Systematic review evidence of five placebo-controlled trials investigating the use of topical NSAIDs suggests that this can offer short-term pain relief up to four weeks but the evidence was judged to be of low quality and therefore inconclusive.¹⁹ The evidence for oral NSAIDs was conflicting. No trials have specifically investigated the use of paracetamol or opioid medication though it stands to reason that these may offer short-term symptomatic pain relief only rather than affecting the overall course of the condition, as found with other musculoskeletal disorders, such as back pain and shoulder pain.¹¹

Evidence for use of physiotherapy interventions

In this section the evidence for these treatments will be analysed and discussed:

Manual therapies

Manual therapy includes a range of different 'hands-on' treatment techniques that, in the case of LET, can be grouped into Cyriax manual therapy, Mobilisation with Movement (MWM) and regional mobilisations.²⁰ The Cyriax method involves a 10-minute session of deep transverse friction massage to the painful tendon followed by a Mills' Manipulation whereby the patient's elbow is forcibly extended to end range whilst the wrist is fully flexed and the forearm pronated.²¹ MWM combines manual therapy with active exercise, typically a lateral glide to the elbow whilst the patient performs an isometric gripping exercise.²² Regional mobilisations include all other types of manual therapy used more generally in the upper limb, rather than focussed on the elbow, and mobilisation of the cervical spine.²⁰

The most-recent systematic review and meta-analysis of manual therapy for LET by Lucado et al²⁰ concludes that "there is compelling evidence that joint mobilizations directed at the elbow improve both pain and functional grip scores across all time frames compared to control groups in the management of LET." This conclusion must, however, be questioned based upon methodological errors and reporting bias in the review. Three large studies are included in the meta-analyses that investigate manual therapy as part of a multimodal physiotherapy treatment package compared with a control of wait-and-see (including advice).^{2,6,23} It is impossible to determine the effect of the manual therapy component of these studies which should not have been included in the meta-analyses for that reason. With these studies removed the meta-analysis of Mills' Manipulation (Cyriax manual therapy) would not be possible for pain as only one study would remain. The meta-analysis of pain for MWM would only include one small pilot study of 10 patients and a small non-randomised study of 34, with no analysis possible for follow-up beyond four weeks.^{24,25} Grip strength would not be possible as only one study would remain.²⁴

Reviewing the remaining evidence descriptively, Cyriax manual therapy is no more effective than Biopton polarised light therapy based upon no significant difference in any outcome measures or time points apart from pain visual analogue scale (VAS) at 28 weeks.²⁶ The same study included an exercise intervention arm and found that exercise was more effective than Cyriax manual therapy at all time points and all outcome measures up to 28 weeks.²⁶ Similarly, Viswas et al²⁷ compared Cyriax manual therapy against the same exercise intervention designed by Stasinopoulos²⁸ and found similar results in favour of exercise. In contrast, Nagrale et al²¹ found Cyriax manual therapy to be superior to a combination diclofenac gel phonophoresis and Stasinopoulos exercises at eight weeks.

Two studies have investigated the immediate effect of MWM on pain free grip strength (PFGS) and pressure-pain threshold (PPT) after a single treatment session.^{22,29} The studies were small, totalling 41 patients, but had robust methodologies that included a placebo and control procedure, and blinded both the patient and the outcome assessor to the intervention. Both found significant immediate improvements in PFGS compared to a sham MWM group and a no intervention group. There are few studies, however, that investigate longer-term effect: two studies investigated the addition of MWM to multimodal physiotherapy including heat, massage and ultrasound therapy. Amro et al²⁴, in a study of 34 patients, found in favour of the MWM group at four weeks follow-up but the method was non-randomised and at high risk of bias. Kim et al²⁵ also concluded that the addition of MWM improved outcome immediately after 10 days of treatment but with just 10 patients the study was under-powered. Afzal et al³⁰ found that patients treated with MWM and ultrasound therapy had significantly improved pain and function at four weeks follow-up compared to those treated with ultrasound alone but the study was limited by a small sample size (n=30) and a lack of blinding. A novel study by Martinez-Cervera et al³¹ investigated the mechanism by which MWM might have an effect. Twenty-four patients were randomised into two groups that both received MWM three times in a week. Half of the patients were told that MWM was a very effective treatment and the other half were given neutral expectations that it may or may not be effective. Patients given high expectations gained significantly better outcomes immediately after treatment suggesting that patient expectation might be an important factor in treatment selection.

Regional mobilisations can be divided into wrist mobilisation and cervical spine mobilisation. The evidence for wrist mobilisation is limited to two small un-blinded studies of similar methodology compared against multi-modal physiotherapy.^{32,33} Both found short-term benefit in favour of wrist mobilisation at three weeks but Struijs et al³³ also followed-up patients to six weeks and found no difference between groups at that time point. The evidence for cervical mobilisation is based upon three small randomised trials totalling 43 patients and one low-quality retrospective study.³⁴⁻³⁷ Vicenzino et al found immediate improvements in PFGS, pain VAS and PPT with mobilisation of the C5/6 cervical levels compared to a sham technique or control.³⁷ Fernandez-Cervaro et al conducted two studies where cervical manipulation was firstly compared with a sham technique and secondly compared with thoracic manipulation.^{35,36} Both reported immediate improvement in PPT but conflicting results for PFGS. The retrospective study by Cleland et al³⁴ concluded that there was a high long-term success rate for multimodal physiotherapy with or without cervical mobilisation. Small differences were seen in favour of cervical mobilisation group but given that the patient demographics and treatments received as part of the multimodal physiotherapy between groups were different the attribution of this effect to manual therapy alone is unjustified.

Overall, there is low quality evidence to suggest short-term benefit of manual therapy but also that it may be less effective than exercise.

Orthoses and Taping

Orthoses

Orthoses for LET are widely available for general public sale and are also provided via the UK NHS on the recommendation of clinicians.³⁸ Different forms of orthotics are available but the two main principles of treatment are either to immobilise the wrist, thus reducing the activity of the wrist extensor muscles, or to alter the mechanical forces along the extensor muscles of the forearm by use of a 'counter-force brace'. Counter-force bracing involves fastening a tight cuff around the forearm containing a padded section that is sited over the ECRB muscle. Cadaveric studies have shown that this reduces the force on the ECRB tendon origin when a load is applied distally, suggesting that *in vivo* the aggravating load on the ECRB might be reduced when performing gripping activities whilst using the brace.³⁹ This has been demonstrated in a small LET patient population where 31 patients were randomised to either wear the brace correctly as a tight cuff or to wear it loosely to minimise the effect.⁴⁰ Those wearing the brace correctly experienced significant pain relief in the short term compared to those wearing it loosely. Likewise, a cross-over study investigating two different types of counter-force brace (one a standard design and another incorporated into an elbow compression sleeve) found that these gave immediate pain relief and improved grip strength compared to no brace.⁴¹

The use of a wrist immobilising splint has been shown to improve pain and grip strength after three weeks when used in combination with physiotherapy treatment and compared to physiotherapy treatment alone.⁴² Two studies have compared the use of counter-force bracing to wrist immobilisation, with different conclusions drawn: Akkurt et al⁴³ found no difference between the different types of splint up to six weeks follow-up of 82 patients whereas Garg et al⁴⁴ concluded that wrist immobilisation was superior at the same time point when studying 42 patients. This conclusion is questionable however, as it was only demonstrated in one sub-domain of the American Shoulder and Elbow Society (ASES) Elbow Assessment Form when all other outcome measures showed no difference. Both studies showed that patients with LET improved over time regardless of which orthosis was used. Van De Streek et al⁴⁵ compared the use of a counter-force brace to both the counter-force brace and wrist immobiliser worn together and found no difference in outcome between groups at six weeks.

Whilst there is some evidence of short-term effect of orthotic use, there may be no effect in the long-term. A large study of 110 patients with LET by Nishizuka et al⁴⁶ compared a counter-force brace worn daily for six months in addition to exercises with exercises alone. There were no differences in outcomes between groups at any time point up to one year, but both groups improved significantly suggesting the brace gave no additional benefit to exercises alone. Similarly, a large study of 185 patients compared the use of a counter-force brace against an exercise programme and found in favour of exercise at all time points up to a minimum of 12-month long-term follow-up.⁴⁷ Indeed, a large retrospective population study of 4614 patients receiving treatment for LET and medial elbow tendinopathy (MET) in the USA found that those using orthoses of any type had higher healthcare usage, longer treatment duration and longer time off normal work than those that did not use orthoses. Other factors may though confound this conclusion as it was unclear whether the baseline symptoms (such as pain severity) were similar between those using orthoses and those not. Higher baseline pain is an established predictor of poorer outcome in patients with LET⁴⁸ so the differences between groups may not be due to orthotic use alone.

Taping

Kinesiology tape (or K-tape) is an adhesive elasticated tape that is purported to reduce the load on the wrist extensor tendons when applied longitudinally over the dorsal forearm muscles.^{49,50} It is not

commonly used in UK practice.³⁸ Studies of the use of K-tape to treat LET are of low quality and of small sample size.^{49,51-55} Cho et al⁵⁰ found that the application of K-tape to patients with LET gave some immediate pain relief for up to 15 minutes but for longer follow-up the majority of studies show that the use of K-tape is no more effective than sham taping techniques or offers no increased benefit when used in addition to other physiotherapy modalities such as exercise.^{49,51,54} The exception is a study by Giray et al⁵⁵ but with only 10 patients per group the result may have been due to chance.

Diamond taping uses a non-elastic adhesive tape applied in four strips pulled tightly around the location of lateral elbow pain to form a diamond, resulting in the encompassed skin having an orange-peel appearance.⁵⁶ Similarly to K-tape it is purported to reduce mechanical load on the wrist extensor tendons.⁵⁶ A recent systematic review identified four studies of diamond taping each only measuring the immediate effect after application or up to 30 minutes afterwards.⁵⁷ All four studies showed improvements in either pain or grip strength compared to controls. It is unclear however whether this has any useful clinical benefit as longer-term effects have not been studied.

Acupuncture

Acupuncture is used by some physiotherapists in the UK as a second-line treatment for LET.³⁸ It involves the insertion of fine needles into specific anatomical points on the body as defined in Traditional Chinese Medicine (TCM). These points are then stimulated in a variety of ways such as by twisting the needles (manual stimulation), applying an electrical current (electro-acupuncture) or by heating the needles (moxibustion).^{58,59} The purpose is to induce a pain-relieving effect on the nervous system although the evidence for this effect has not been firmly established.⁵⁹

The evidence for the use of acupuncture in the treatment of LET is of low or very low quality based upon several systematic reviews.^{58,60-62} Of the included studies, only four compare acupuncture with a supposed placebo or sham treatment. It might be argued, though, that in three of these studies the control arm still included acupuncture treatment: Fink⁶³ and Irnich⁶⁴ both used a similar method whereby acupuncture needles were still inserted but at least 5cm away from the sites recommended by TCM; in the study by Haker⁶⁵ needles were still inserted at acupuncture sites but only superficially rather than to the recommended depth, and were not stimulated. In the fourth study, Molsberger⁶⁶ used a sham control method where pressure was applied to an acupuncture point on the patients' thoracic spine with a pencil-shaped probe instead of a needle being inserted but patients could not be blinded from this as the 'real' acupuncture group did not have any needles inserted in the thoracic region. Despite this, in all four of these studies outcomes favoured 'real' acupuncture immediately post-treatment or up to two weeks' follow-up. A limitation of the majority of acupuncture studies is the lack of longer-term follow-up, lack of blinding, lack of randomisation and heterogeneity of outcome measures that prevents meta-analysis of data.⁵⁸ Few studies measure the impact on disability and function, just focussing on pain severity.⁶² Fink⁶³ and Haker⁶⁵ both followed-up patients for one year but no significant differences were seen between 'real' acupuncture and sham acupuncture beyond two weeks. Improvements were seen in both groups following the natural trend for improvement in LET symptoms over time. The evidence for acupuncture treatment for LET is therefore uncertain but it may offer some short-term benefit for pain for up to two weeks.

Electrotherapies

Electrotherapy was established as one of the four pillars of UK physiotherapy practice when the Society of Physiotherapy was granted its Royal Charter in 1920. Over the century that followed electrotherapies changed with evolving technology but the principle of the purported mechanism of effect remained the same: when energy is focussed on injured tissue it can improve the healing response.⁶⁷⁻⁷¹ Electrotherapy is still used in the management of LET in the forms of laser, ultrasound and shockwave therapy (SWT).^{38,72}

Laser

Laser treatment uses light energy applied locally to the area of pathology to stimulate a physiological response such as reducing inflammation or promoting collagen production.⁷³ The reaction is dose-dependent with collagen production at lower doses and anti-inflammatory effects at higher doses.⁷³ For this reason Low Level Laser Therapy (LLLT) is most commonly used in the treatment of LET to promote collagen repair in the absence of significant inflammation.⁷⁴ Laser light can be generated at different wavelengths dependent on the elements used: gallium arsenide 904nm, helium neon 632nm, gallium aluminium arsenide 820nm and neodymium-doped yttrium aluminium garnet 1064nm.^{67,75,76} These different wavelengths penetrate human soft tissues differently with 904nm having the deepest effect.⁷⁷ The use of laser was popular in the 1990s but has since declined in both usage and availability.⁷⁸ Recent studies of UK practice showed that it was now scarcely used in the treatment of patients with LET.^{38,72}

A systematic review of the effectiveness of LLLT in the treatment of LET published in 2008, Bjordal et al⁷³ concluded that it offered favourable short-term improvements in both pain and function when compared to placebo. In a previous review, Bisset et al⁷⁹ had concluded that laser was no more effective than placebo but in this study the analysis was not broken down into different treatment wavelengths. Bjordal et al⁷³ sub-classified studies by treatment wavelength in their meta-analysis to find that the 904nm wavelength provided an effective response (when applied over the extensor tendons rather than when applied over acupuncture points) immediately after the course of treatment and up to eight weeks of follow-up. The 820nm and 1064nm showed no benefit and the 632nm wavelength was inconclusive but might be effective based upon one study.⁸⁰

Ultrasound

Ultrasound therapy delivers energy locally to the tissues via high frequency sound waves. The evidence for ultrasound is conflicting and of low or very-low quality.^{60,61,71,81} Smidt et al⁸¹ in a systematic review published in 2003 pooled data from two studies to conclude that ultrasound was effective for pain relief in the medium-term up to 13 weeks but the studies were low-powered. Indeed, considered separately these two studies show conflicting results: Binder et al⁸² demonstrated significant benefit from ultrasound over placebo whereas Lundeborg et al⁸³ found no difference. A subsequent study of similar methodology comparing ultrasound against placebo also found no difference in outcome.⁶⁹ Subsequent reviews in 2014 and 2015 have concluded that ultrasound is no more effective than placebo in the short-term.^{71,84} However, Dingemanse et al⁷¹ still concluded that there was moderate evidence in favour of ultrasound over placebo in the medium-term despite this being based on the outcome of just one study that could not be replicated.

Shockwave therapy

Shockwave therapy provides energy to the tissues via pulsed acoustic waves, but the mechanism of any therapeutic effect is unclear.⁷⁰ Shockwave therapy can be administered in different ways: by use of a radial shockwave device or an extracorporeal shockwave device, and with or without the

addition of local anaesthetic. One method has not been shown to be superior to the others.⁸⁴ The continued clinical use of SWT is surprising given the conclusions of a 2006 systematic review stating that based upon “platinum-level evidence that shock wave therapy provides little or no benefit in terms of pain and function in lateral elbow pain.”⁷⁰ A more recent review published in 2015 pooled data from the 2006 review with subsequent studies to draw similar conclusions: that SWT was no more effective than placebo for pain or pain on resisted wrist extension up to six weeks follow-up.⁸⁴ Despite this, it continues to be used in UK practice for the treatment of LET by 11% of respondents to a recent nationwide survey.³⁸

Exercise therapy

Exercise is the mainstay of modern physiotherapy treatment of LET in the UK.^{38,72} A limitation of the evidence regarding exercise is the heterogeneity of exercise type, treatment duration and dosage used in clinical trials.⁸⁵ Many trials have used bespoke exercise programmes but there are four specific exercise protocols have been studied multiple times:

The Pienimaki protocol

The Pienimaki protocol was first described in 1996 in a trial of exercise versus ultrasound therapy.⁸⁶ It consisted of stretches of the forearm muscles and a four-stage progressive loading regime starting with isometric contractions, then isotonic resisted uniplanar exercises using a Theraband, followed by isotonic resisted biplanar exercises using a Theraband, and finally functional repetitive movements involving gripping. Patients were advised to perform exercises four to six times per day for six to eight weeks. Each exercise was done in two to three sets of 10 repetitions. The findings of the trial showed that the exercise protocol was significantly more effective than ultrasound immediately after eight weeks of treatment.

The same exercise protocol was subsequently used with deep transverse friction massage and ultrasound as part of a multimodal physiotherapy treatment package by Smidt et al.⁴ The multimodal package gave the highest chance of recovery at six months compared to corticosteroid injection or wait-and-see.

It was also used by Tonks et al⁸⁷ in a low-powered randomised controlled trial (RCT) involving 12 patients per group. Improvements were seen at seven-week follow-up in pain and grip strength compared to controls but failed to reach statistical significance.

The Stasinopoulos protocol

Stasinopoulos et al^{26,28} described a four-week supervised exercise protocol consisting of one stretching exercise and a progressive eccentric loading exercise. A stretch of the wrist extensor muscles was performed with the elbow extended, forearm pronated and wrist passively flexed with ulnar deviation to the end of the available range. The position was maintained for 30-45 seconds and repeated three times before and after the eccentric loading exercise. Eccentric loading was performed with the elbow fully extended and forearm pronated whilst supported on a treatment couch. The wrist was passively positioned into full extension then slowly lowered to full flexion over 30 seconds with the addition of a load individualised to the patient. The load was applied using a weight or Theraband and determined by the pain response. Mild pain was acceptable but disabling pain meant that the load was too great. Eccentric exercises were performed in three sets of 10 with a one-minute rest period in-between sets.

The Stasinopoulos protocol has been used in seven trials.^{21,26,27,88-91} It has been compared to the Pienimaki protocol and found to give greater benefit in terms of pain relief and function at 12 and

24-week follow-up.⁹⁰ Patients performed supervised exercises once per day, five days per week for four weeks compared with home exercises four to six times per day for eight weeks in the Pienimäki protocol. Adherence to home exercise was not measured but the authors hypothesise that adherence may have been the deciding factor in why the Stasinopoulos protocol was more effective. An alternative reason could be the different types of exercise used.

Three studies have compared the Stasinopoulos protocol to Cyriax manual therapy.^{21,26,27} The two studies that used the protocol as a stand-alone treatment found it to be superior to Cyriax manual therapy^{26,27} but Nagrale et al²¹ combined it with diclofenac gel phonophoresis and found it to be less effective.

Manias et al⁸⁸ investigated whether the addition of ice massage to the exercise protocol was more effective than the exercises alone and found no difference in outcome. Both Sethi et al⁸⁹ and Mostafaei et al⁹² added shoulder strengthening exercises to find that these further improved outcomes when compared to the Stasinopoulos protocol alone. Likewise, the addition of concentric and isometric strengthening exercises resulted in superior short-term results when compared to the original protocol.⁹¹

The Solveborn protocol

The Solveborn protocol⁴⁷ consisted of 10-second isometric wrist extension contractions followed by stretches of the forearm extensor muscles held for 15-20 seconds. Isometric contractions were performed three to five times followed by a similar number of stretches. Then, similar exercises were performed for the wrist flexors. Pain during exercise was avoided. Exercises were performed twice daily. In a large trial of 185 patients, the exercise protocol was compared with the use of a counterforce brace. Both groups improved but the exercise group had significantly better outcomes at all time points up to and beyond a year follow-up.

The protocol was used in three other trials.⁹³⁻⁹⁵ Nilsson et al⁹⁴ taught the exercise protocol for home use along with ergonomic advice and a counterforce brace in a non-randomised trial versus a control of usual care. The intervention group had significantly better outcomes at four and 16-week follow-up but there was a high drop-out rate in the control group that may invalidate the results. Haahr et al⁹³ conducted a large RCT involving 266 patients randomised to a one-off education session, including general advice and instruction in the Solveborn protocol, versus a control group of usual care. They found that both groups improved up to one year but with no between-group difference. Svernlöv et al⁹⁵ compared the Solveborn protocol to a combination of stretching and progressive eccentric loading. The same stretching dose was used but the isometric exercises used in the Solveborn protocol were substituted with three sets of five repetitions of pain-free eccentric loading exercises using a weight. Each repetition was performed over 10 seconds. The weight was progressively increased by 10% each week from a starting point of 1 kilogram for males and 0.5 kilograms for females. Both groups exercised at home for 12 weeks. Improvements were seen in both groups but the eccentric exercise group gained significantly improved grip strength at six months compared to the Solveborn protocol group.

The Vincenzino protocol

The Vincenzino protocol⁹⁶ has been used in three large RCTs totalling 483 patients.^{2,23,97} In all three trials it has been used as part of a multimodal approach along with manual therapy and taping. The exercise component required patients to perform pain-free exercises of the hand, wrist and forearm starting with simple controlled active movements not incorporating additional load. Load was then progressively added using Therabands of increasing resistance during concentric and eccentric actions of the wrist. The focus was on wrist extension with exercises performed slowly over six to

eight seconds. The dose was dependent on the symptom reaction with pain avoided during and after the exercises. As symptoms improved with gripping no-longer painful, additional strengthening exercises of the whole upper limb were prescribed including bench press, shoulder press, bent-over rows, biceps curls and tricep curls using weights. In two trials patients attended eight times over six to eight weeks^{2,23} and in one trial four times over four weeks.⁹⁷ Significant improvements were seen between four and 26 weeks follow-up across the trials compared to controls and economic evaluation from the trial by Coombes et al found it to be a cost-effective treatment for LET.⁹⁸

Isometric exercises

Isometric exercise as an initial treatment for the management of acute tendinopathy is currently *en vogue*.⁹⁹ Two studies have investigated isometric exercises specifically for the treatment of LET.^{5,100} Park et al¹⁰⁰ randomised 31 patients to early pain-free isometric wrist extensions or the same exercises started after four weeks. The contractions were held for 10 seconds and repeated 50 times, four times a day. Significant improvements were seen in the first four weeks in the early exercise group. Vuvan et al⁵ compared a single session of isometric exercise instruction versus wait-and-see in a trial of 40 patients. Patients were taught to perform the exercises at 20% of the Maximum Voluntary Contraction (MVC) of the unaffected arm increasing to 35% MVC by week seven. They performed three repetitions of 45 second holds or four repetitions of 30 second holds once daily for eight weeks. Outcomes measured using the PRTEE improved significantly in exercise group at eight weeks but other measures did not show a significant difference. The authors concluded that isometric exercise alone was not sufficient to treat LET but may form part of a treatment package.

Stasinopoulos et al⁹¹ compared their own protocol of eccentric and stretching exercises to the addition of concentric exercises and both concentric and isometric exercises. A small and insignificant difference was seen with the addition of concentric exercises but the further addition of isometric exercises resulted in significant improvements compared to eccentric and concentric/eccentric exercises. The study was, however, limited by a small sample size of 34 so the results should be taken with caution.

Eccentric exercises

The most commonly studied form of exercise for LET is eccentric exercise.⁸⁵ A 2020 systematic review by Chen et al¹⁰¹ showed a large effect of eccentric exercise over other treatment modalities or other forms of exercise but noting that in many studies the eccentric exercise was used as part of a multimodal treatment. There are several studies though that have investigated eccentric exercise in isolation. Tyler et al¹⁰² compared a multimodal approach with and without eccentric exercise using a Theraband Flexbar device. It was a small study of 21 patients but the addition of eccentric exercises significantly improved outcomes after six weeks of treatment. The same technique was used by Tiwari¹⁰³ and compared to concentric and eccentric exercises using a weight, performed daily. After the three weeks of treatment outcomes significantly favoured the Theraband Flexbar technique but the difference may be attributable to dosing rather than technique as patients using the Theraband Flexbar performed 45 repetitions per day compared to 20 repetitions in the other group.

In contrast, Martinez-Silvestrini et al¹⁰⁴ compared stretching against stretching with the addition of either concentric or eccentric exercises. They found that all groups improved a similar amount at six-week follow-up although the eccentric exercise group suffered fewer exacerbations of symptoms.

Soderberg et al¹⁰⁵ treated 42 patients using a counterforce brace with and without the addition of eccentric wrist extension exercises. A simple method was employed where patients exercised at home holding a bucket with increasing amounts of water to increase load. After six weeks of follow-up the group performing eccentric exercises had significantly better outcomes.

A higher quality study by Crosier et al¹⁰⁶ randomised 92 patients to a multimodal physiotherapy treatment package of ice, TENS, ultrasound and stretching exercise versus multimodal physiotherapy plus eccentric exercises. The eccentric exercises involving wrist extension and forearm supination were performed using a Cybex isokinetic machine three times a week for a total of 25 to 26 sessions. Two sets of 10 exercises were performed for each movement with gradually increasing velocity and resistance over the treatment period up to 90° per second and 80% MVC. Significantly improved results were seen in the eccentric exercise group at the end of treatment but the practicality of an intervention requiring high levels of patient attendance must be questioned.

Other exercise protocols

Peterson et al³ used a similar method to Soderberg et al¹⁰⁵ teaching patients to exercise at home using a bucket filled with water in a trial comparing exercise to a wait-and-see approach. The exercise protocol used concentric and eccentric wrist extension with progressive load, starting with 2kg for males and 1kg for females. Patients performed three sets of 15 repetitions daily and increased the load by 0.1kg each week for three months. Patients in the exercise group had significantly better outcomes than wait-and-see at three-month follow-up. The same authors then performed a second study of 120 patients splitting the protocol into eccentric exercise only versus concentric exercise only.¹⁰⁷ The eccentric exercise group achieved a faster and greater improvement in pain.

Selvanetti et al¹⁰⁸ used a home exercise combination of contract/relax stretching and eccentric loading of the wrist extensors in a trial against a control intervention of ultrasound and advice. Only the abstract is available in English, but at minimum six-month follow-up a large treatment effect was seen in the exercise group, significantly greater than controls.

Barratt et al¹⁰⁹ conducted a large service improvement project involving 182 patients. Firstly, usual care was assessed before a shift of focus was made towards strengthening exercises and finally a specific progressive loading protocol implemented. The protocol began with moderate to high load isometric exercises progressing to concentric and eccentric exercises with increasing load. Although the study was limited by its non-randomised design and loss to follow-up there was evidence that the specific progressive loading protocol was more effective than other care with the difference attributed to the higher load progressions of the specific protocol. Indeed, a systematic review of tendon adaption to loading concluded that it was the progression to high load exercise that is the key factor in stimulating a tissue response rather than the type of muscle contraction used during exercise, though this review only included studies of lower limb tendinopathy.¹¹⁰

Exercise dosing

Raman et al⁸⁵ conducted a review of the literature in 2012 regarding the choice of exercise and dosing used to treat LET. The findings demonstrated great heterogeneity in numbers of repetitions, sets of exercises, frequency of exercise and duration of the exercise course with no clear conclusion on the optimum level. In a more recent 2020 review focussed upon eccentric exercise only, Chen et al¹⁰¹ found that exercises were typically performed in three sets of 10 to 15 repetitions separated by 30 seconds to a minute's rest between each set. Exercise frequency ranged from three days per week to daily and the duration of treatment from three weeks to 12 weeks. Based upon theoretical healing times for tendon pathology and assessment of treatment effect size of high dose versus low

dose trials the authors' recommendation was to perform eccentric exercises at least once per day, in three sets of 10-15 repetitions, for a minimum period of six weeks.

Painful versus pain-free exercise

A systematic review of pain-free exercises versus exercises that allowed some level of pain, published in 2017, found a short-term benefit in favour of painful exercises up to three months.¹¹¹ The review does not contain any trials related to LET but six of the nine included trials related to tendinopathy so the findings may be transferrable. Pain-related fear can lead to central sensitisation of the nervous system resulting in higher perceived pain levels, so an exercise approach that focusses on avoiding pain may exacerbate this response.¹¹² Central sensitisation is a common feature in patients with LET, as identified by 10 studies included in a recent systematic review so needs to be considered in any intervention design.¹¹³ Methods of addressing central sensitisation and pain-related fear have been proposed for clinical practice and can be applied to exercise interventions for LET.^{112,114} These include education of the patient, addressing anxiety related to activity or exercise to reduce the threat response and graded exposure to painful activities. The Stasinopoulos protocol permits mild pain during exercise below 4/10 on a numerical rating scale (NRS) and includes graded exposure to a painful stimulus (loading of wrist extension using a weight) with gradual progression of increasing load. It was consistently effective in treating LET in seven trials, so might be a basis of this theory if applied to practice with additional patient education.^{26-28,88-91}

Exercise Summary

Eccentric loading is the most frequently studied form of exercise for LET and appears effective, with some certainty in the short-term based upon trials of moderate quality. There is additional evidence for the supplementation of eccentric loading with isometric and concentric exercises to amplify the effect. Based upon modern understanding of pain science and previous trials involving pain-provoking exercise there is justification to encourage exercise into low levels of pain if supported by appropriate patient education.

Corticosteroid injections

The use of corticosteroid injection (CSI) to treat patients with LET is controversial with calls to stop made as long ago as 2010.¹¹⁵ Despite this, a survey conducted in 2011 still showed that 48% of UK specialist clinicians used CSI as a primary treatment.¹¹⁶ Whilst this number had declined in a similar UK survey conducted in 2017, 36% of respondents still used CSI as a first or second-line treatment.³⁸ The controversy stems from the conclusions of several large randomised controlled trials that showed worse outcomes at one year follow-up compared to patients treated without CSI.^{2,4,23} Numerous studies consistently showed a significant reduction in pain up to six weeks following CSI with a large effect size.¹¹⁷ This significant short-term effect may be attractive to patients as it can provide fast alleviation of symptoms and allow early return to work but the longer-term implications need to be considered. Mardaini-Kivi et al¹¹⁸ found that the symptoms of 34.7% of patients had already returned 12 weeks after CSI. Bisset et al² compared CSI to multimodal physiotherapy or a wait-and-see approach that included general advice. At six weeks, CSI produced the greatest improvement but by 12 months had the worst outcome, even when compared to wait-and-see. The CSI group had a 72% recurrence rate at 12 months compared to just 8% with physiotherapy and 9% with wait-and-see. Coombes et al²³ compared CSI with a saline placebo injection and multimodal physiotherapy versus no physiotherapy in a 2 x 2 factorial design study. The two CSI groups showed the greatest improvements at four weeks but the worst outcomes at 12 months, even when

compared to the placebo injection and no physiotherapy. The recurrence rate at 12 months was 54% across the CSI groups. A subsequent economic evaluation from the same study concluded that CSI was not a cost-effective treatment for LET.⁹⁸ Smidt et al⁴ compared CSI to multimodal physiotherapy or a wait-and-see approach. Again, CSI produced the greatest improvement at four weeks but by 12 weeks was no better than wait-and-see. At six months and one year the outcomes for those patients receiving CSI were worse than wait-and-see. Of the large randomised controlled studies of CSI for LET, it is only Hay et al¹¹⁹ and Olausen et al⁶ that did not show a detrimental effect at one year follow-up. Hay et al¹¹⁹ compared CSI to naproxen tablets or placebo vitamin C tablets. Olausen et al⁶ compared CSI plus multimodal physiotherapy with a placebo injection plus multimodal physiotherapy and a third wait-and-see group. By 12 months all groups had achieved a similar outcome but after an initially favourable response the CSI plus physiotherapy group had worse outcomes between 12 to 26 weeks compared to the other groups. Overall, the evidence would suggest therefore that CSI should be used with caution as despite strong evidence of short-term beneficial effect, the medium-term and long-term effect may be negative.

Multimodal physiotherapy

Many studies use a combination of treatments as part of a multimodal package of physiotherapy treatment. In particular, there are five large randomised trials totalling 845 patients, four of which had wait-and-see control groups, that have investigated a multimodal approach with a long-term follow-up of one year.^{2,4,6,23,97} Three of these trials used the same multimodal approach proposed by Vicenzino in 2003.^{2,23,96,97} Patients were educated regarding avoiding painful activities involving repetitive activity or gripping with the forearm pronated and elbow extended. A trial of MWM and taping was performed to establish if there is an immediate reduction in pain on gripping and patients were taught an exercise routine of posture correction, progressive forearm strengthening and general upper limb strengthening. Patients were then seen eight times over six to eight weeks in two trials^{2,23} and four times over four weeks in one trial.⁹⁷ At these visits MWM and taping was repeated if found to be beneficial and the exercises were repeated under supervision and progressed as able. Exercises were continued at home. All three trials found significant short-term improvement with multimodal physiotherapy between four to six-week follow-up compared in two trials to a control of wait-and-see, and in one trial to prolotherapy. Additionally, Coombes et al²³ found multimodal physiotherapy superior to wait-and-see at 26 weeks and Yelland et al⁹⁷ superior to prolotherapy at 12 weeks. All three studies found that by 12 months the difference between control or prolotherapy was no-longer significant due to the fact that LET symptoms tend to improve in the majority of patients over time. Bisset et al², though, performed an area under the curve analysis to evaluate that, compared to CSI or a control of wait-and-see, multimodal physiotherapy was superior. It was also associated with the lowest symptom recurrence rate and lowest analgesic use.

Olausen et al⁶ compared multimodal physiotherapy with CSI or placebo injection against a control group of wait-and-see. The multimodal physiotherapy consisted of six sessions over six weeks of Cyriax manual therapy, passive stretches of the forearm extensor muscles and a home exercise programme of forearm extensor muscle stretching and eccentric strengthening. The wait-and-see group were given education regarding activity modification and were prescribed NSAIDs. At six-week follow-up multimodal physiotherapy was superior to wait-and-see but at subsequent assessments at 12, 26 and 52 weeks there was no difference between groups.

Smidt et al⁴ compared multimodal physiotherapy against CSI and a control group of wait-and-see. The multimodal approach consisted of ultrasound, deep transverse friction massage and the

Pienimäki exercise programme of stretching and progressive strengthening for six weeks.⁸⁶ The highest probability of recovery at six-month follow-up was found in the multimodal physiotherapy group. At 12-months the success rate of the CSI group was 69% compared with 91% and 88% respectively in the multimodal physiotherapy and wait-and-see groups.

Overall, the evidence would suggest a positive short and mid-term effect of multimodal physiotherapy compared with control or comparator treatments but the key components of an optimum multimodal physiotherapy treatment package have not been established.

Summary

A wide range of treatment techniques have been investigated for LET. There is low or very low-quality evidence to suggest that manual therapy, laser, acupuncture, diamond taping and orthotics may give a short-term beneficial effect but the practicalities of using such interventions in a publicly-funded health service are questionable. There are uncertainties regarding the value of treatments that require numerous patient attendances, such as manual therapy, laser, taping or acupuncture. Exercise is supported by a greater evidence base but questions remain as to the optimum exercise choice and exercise dose. Stretching and eccentric exercise show beneficial effects but with the potential for further improvement with the addition of isometric and concentric exercises. Modern understanding of pain theory would suggest that exercise into mild pain might also improve outcomes. Trials have shown that many patients improve with simple advice and time, but there is potential to improve this self-management support further with the addition of psychological and behavioural interventions to improve patient self-efficacy.

Given the current lack of a consistent treatment approach provided in the UK and lack of certainty from the evidence base to guide clinicians, it is necessary to ascertain from clinical, managerial and patient stakeholders which are the most practical treatments for use in UK NHS practice as part of an optimised physiotherapy treatment package.
