ABSTRACT

Objectives: To evaluate the diagnostic accuracy of a combination of qualitative and quantitative measurements of shear wave elastography (SWE) to detect malignancy in patients with pathological nipple discharge (PND).

Design: Prospective diagnostic accuracy study comparing a combination of qualitative and quantitative measurements of SWE (index test) to a microdochoctomy for histological diagnosis (reference test).

Setting: Fuzhou general hospital of Nanjing military command.

Participants: A total of 227 patients with PND were finally included from January, 2011 to March 2014, after we screened 1084 possible candidates. All participants were evaluated through a SWE with qualitative parameters generated by Virtual Touch™ tissue imaging (VTI) and quantitative parameters generated by Virtual Touch™ tissue quantification (VTQ). All the patients were consented to receive microdochoctomy for histological diagnosis, and the results were set as a reference test.

Outcome measures: Sensitivity and specificity of the combined VTI and VTQ of the SWE for detection of malignancy in patients with PND.

Results: The 227 participants presented with 237 lesions. The results of pathological examination showed that 159(67.1%) of the 237 lesions were benign and the other 78 (32.9%) were malignant. An area under the curve (AUC) of elasticity score, VTQm and VTQc were 0.854, 0.826, 0.856 respectively, with the corresponding cut-off point as 2.50, 3.285m/s and 3.445m/s respectively. After a combination of these measurements, the sensitivity, specificity, positive and negative

predictive value (PPV and NPV) were 82.1%, 96.9%, 92.8% and 91.7%, respectively.

Conclusion: A combination of qualitative and quantitative measurements of SWE is predictive for detecting malignancy in patients with PND. However, the generalization of this method is limited because of the highly selected study population.

Key words: Shear wave elastography; Pathological nipple discharge; Microdochoectomy; Breast Imaging- Reporting and Data System.

Strengths and limitations of this study

- Accuracy of the combined measures of shear wave elastography (SWE) for detecting malignancy of PND patients has never previously been studied.
- For the first time, this study tested diagnostic accuracy of the combined measures of SWE for detection of malignancy in PND patients.
- Limitations include that we excluded patients without a positive ductoscopy findings, which might overestimate the diagnostic accuracy of elastography in PND patients

Introduction

According to the 2014 cancer statistics of the American cancer society, the new cases of breast cancer are 235030, accounting for 40430 deaths[1]. The prevalence of breast cancer ranks the highest in Chinese women with malignant carcinoma[2]. The number of Chinese women with breast cancer account for 12.2% of all newly diagnosed breast cancer and 9.6% of deaths from it around the world[2].

Pathological nipple discharge (PND) is the third most common complaint of patients prompting

1
2
3
4
5 referral to doctors for breast diseases[3]. PND is believed to be an indicator for breast carcinoma,
6
7 especially when the nipple discharge is bloody[3]. So mastectomies were carried out unnecessarily
8
9 without obtaining a histopathological diagnosis before the year 1950. Although mastectomies are
10
11 not necessarily needed nowadays, patients with PND would be normally suggested to take further
12
13 examinations to rule out malignancies. These examinations involve mammography, ultrasonography,
14
15 ductoscopy with or without galactography, as well as cytological examination. Mammography and
16
17 B-mode ultrasonography are used for screening patients with high risk of breast carcinoma, but
18
19 they are not sensitive enough for detecting malignancy in PND patients, since small lesions may be
20
21 occult on these 2 modalities[4]. Ductoscopy may miss the malignant lesions outside a depth of
22
23 2cm[5], and cytological could only be used as supportive tests [6].
24
25
26
27
28

29
30 Ultrasonography elastography work through the assumption that tissue compression produces
31
32 strain within the tissue, and that the strain is smaller in firm tissue than in soft tissue. So through
33
34 measuring tissue strain ratio, we could evaluate the firmness of the tissue to predict malignancy of
35
36 masses. Recently, several studies indicated that ultrasonography elastography may be a useful tool
37
38 for differentiating benign and malignant masses. The sensitivity of the predicting a malignancy in
39
40 patients complaining breast lesions ranges from 80% to 98%, while the specificity ranges from 66%
41
42 to 84%[7-12]. Recently, a shear wave elastography is reported to be less operator-dependent and
43
44 predictive of ductal or intraductal carcinoma[13-15]. A five-level elasticity score is normally used for
45
46 qualitative assessment of the images of elastography, while a quantitative measurement of
47
48 elastography is also becoming popular; a combination of these ultrasonic measurements seems to
49
50 be beneficial for improving diagnostic accuracy of breast malignancies[14 15]. We noticed that the
51
52
53
54
55
56
57
58
59
60

diagnostic value of a combination of qualitative and quantitative measurements for elastography to detect malignancies in patients with PND has rarely been studied. So we conducted a study aiming to find out the sensitivity and specificity of the combination measurements for predicting malignancy in patients with PND.

Methods and materials

This is a study designed for evaluating diagnostic sensitivity and specificity of shear wave elastography (SWE) for detection of malignancy in patients with PND. This study protocol was approved by the ethical review board in Fuzhou general hospital of Nanjing military command (No. FZJQ2011018).

Patients

Patients who complained a PND within 1 year were recruited from outpatient settings in the Fuzhou general hospital of Nanjing military command. The patients were screened for eligibility according to the following inclusion criteria: (1) with an age over 18 years; (2) with or without palpable breast masses; (3) with breast masses detected by B-mode ultrasonography; (4) agree to participate in this study; (4) providing a written consent for further examination, biopsy and use of the study data. We excluded the participants who (1) refused to receive a microdochectomy or a biopsy; (2) had serious damage in internal organs that may bias the results; (3) could not receive local anesthesia because of allergy; (4) were taking or have taken chemotherapy or radiotherapy for suspicious malignant breast tumors.

Ultrasonography imaging

A B-mode ultrasonography (BUS) and an elastography using acoustic radiation force Impulse (ARFI)

1
2
3
4
5 were performed with a Siemens ACUSON S2000 ultrasonography system (Siemens Ltd., China,
6
7 product standard: YZB/USA 3876-2010). One operator (with 10 years of experience in
8
9 ultrasonography imaging) ran the BUS and the ARFI to get the ultrasonography and elastography
10
11 images, using a superficial probe (9L4, Siemens Ltd., China) with a frequency of 4 to 9 Hz.

12
13
14 The BUS images of the breast lesions were obtained and categorized according to Breast Imaging
15
16 Reporting and Data System (BI-RADS). Moreover, we applied a subclassification scheme for BI-RADS
17
18 4: (1) 4A: low suspicious for malignancy; (2) 4B: intermediate suspicious for malignancy; (3) 4C:
19
20 moderate concern, but not classic for malignancy [16]. Two radiologists (XBG and YL who are with
21
22 at least 5 years of experience in ultrasonography) independently assessed the BUS images in the
23
24 following aspects: the shape of the mass, depth, orientation, margin, boundary of the lesions, echo
25
26 pattern, posterior acoustic features, as well as surrounding tissue changes. All the detected masses
27
28 were divided into two types (solid and cystic) according to the presence of a cystic portion. In cases
29
30 involving a solid mass in a dilated duct (intraductal) or cyst (intracystic) with a predominant cystic
31
32 portion, the radiologists considered the cases as cystic type lesions.

33
34
35 After the BUS examination, the operator switched the ultrasonic mode to the virtual touch™
36
37 quantification (VTQ). The patients were told to hold the breath, when the operator detected the
38
39 inside and margin of the lesion, with a previous set region of interest (ROI) in a fixed region of
40
41 5×5cm. The operator recorded the value of VTQ (m/s) and the depth of the ROI (cm) from skin for
42
43 each measurement, in a total of 5 measurements. We calculated the mean value of the 5
44
45 measurements as the final VTQ score. Additionally, the value of VTQ was measured at both the
46
47 margin (VTQm) and center (VTQc) of the breast lesions. Measurable shear wave velocity (SWE)

1
2
3
4
5 ranges from 0 to 9 m/s, a value of ROI exceed the range would be shown as "X.XX m/s" on the
6
7 screen. The participants with this "X.XX m/s" value were excluded.

8
9
10 After finishing examination with the VTQ mode, the operators switched to virtual touch™ imaging
11
12 (VTI). ARFI sequences were generated to evaluate the elasticity scores of the breast lesions in VTI
13
14 mode. The VTI images were evaluated and categorized through a five-level scoring system[17]. An
15
16 elasticity score of 1 indicates strain in the entire hypoechoic lesion (the entire lesion was equally
17
18 shaded in green); score 2 indicates that strain is not seen in part of the hypoechoic (the lesion is
19
20 shown as a mosaic of green and blue); score 3 indicates that strain is in the peripheral areas only
21
22 (peripheral areas in green); score 4 indicates no strain in the entire hypoechoic area (lesion is
23
24 shown in blue); score 5 indicates no strain in the entire hypoechoic lesion or the surrounding
25
26 area(both the entire hypoechoic lesion and its surrounding area were blue). A higher score
27
28 indicates a harder tissue, vice versa. For cystic-type lesions, we analyzed elasticity scores in solid
29
30 areas. After B-mode ultrasonography and ARFI elastography examination, 2 radiologists
31
32 independently reviewed the images and the measurements without knowing the medical history of
33
34 the patients; any discrepancy happened was solved by discussion.

45 Microdochoectomy and pathological examination

46
47 Microdochoectomy was performed to get a biopsy sample, which was set as a reference test (the
48
49 golden standard). The patients were asked to be prepared in supine position with the arm
50
51 preferably extended on a side board. After skin disinfection, the fluid-producing ducts were
52
53 identified by massaging the breast towards the nipple. After dilating the target ducts with lacrimal
54
55
56
57

1
2
3
4
5 dilators, a surgeon (with 5 years of experience in microdochoectomy) introduced endoscope (a
6
7 fiberoptic ductoscopy, 0.8mm of sheath, 80mm of length; manufactured in Denzlingen, Germany)
8
9 through the ducts. After insertion of the ductoscopy, saline was injected into the ducts to keep
10
11 them expanded. The ductoscopy was advanced through the ducts under direct vision from the
12
13 endoscope camera, all tiers of branches were examined until the endoscope could not be advanced
14
15 further or an obstructing lesion was detected. When an obstructing lesion was found, the image of
16
17 this lesion would be taken using an endoscope camera, moreover, an endoscopy guided biopsy
18
19 would be performed as scheduled. After biopsy and image taken, the patient would be referred to a
20
21 surgeon for further treatment advice.

24
25
26

27 After detection of ductal lesions, methylene blue was injected into the discharged mammary duct.
28
29 Local anesthesia was performed and then an incision around the areola was implemented. The
30
31 pathological duct was separated according to tissue with methylene-blue stain, and the duct was
32
33 then dissected and excised. The operator then pulled the clip out of duct together with the scope
34
35 and after the excision was made. The biopsy samples over 1 mm³ were fixed using formalin after
36
37 sample collection, and were sent for histologic examination.

45 Statistical analysis

46
47 Statistical analysis was performed to specify the diagnostic sensitivity and specificity of a
48
49 combination of VTI and VTQ measurements for elastography to predict malignancy in patients with
50
51 PND. First, we would assess the interobserver variability between the two radiologists (XBG and YL)
52
53 using the Cohen's kappa test. The value of kappa over 0.75 was considered as excellent, 0.40 to
54
55
56
57
58
59
60

0.75 as fair to good, and below 0.40 as poor. Second, we evaluated if elasticity score, VTQm and VTQc were independent predictors using a logistic model. In the model, we used differentiation of benign and malignant breast lesions as dependent variable, and the elasticity score, VTQm and VTQc were set as covariates. Third, we calculated the sensitivity, specificity and the area under the curve (AUC) of elasticity score, VTQm and VTQc using receiver operating characteristics (ROC) curve. A valued of AUC of 0.5 was considered as no diagnostic value; 0.5 to 0.7, low diagnostic value; 0.7 to 0.9, mediate diagnostic value; 0.9 to 1.0, high diagnostic value[18]. We calculated the cut-off point of VTQ and gave the respective sensitivity and specificity, based on the highest sum of sensitivity and specificity. According to the cut-off point of each quantitative measurements, we synthesized the measurements by the following formula: the synthesized score=elasticity score + VTQm + VTQc. A synthesized score of 1 was given, if a value over the cut-off point was observed in a breast lesion; otherwise, a score of -1 would be given. A breast lesion with a final score below 0 was classified as benign, otherwise it would be categorized as malignant. Fourth, after differentiating benign and malignant lesions using the synthesized score, we evaluated the sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV). The diagnostic value of this synthesized quantitative measurement was compared with the biopsy results using McNemar analysis. All statistically analysis was performed using Statistical Package for the Social Sciences (SPSS, Version 20.0, Armonk, NY: IBM Corp.) and R software (www.r-project.org, version 3.1.1).

Results

A total of 227 patients with PND were included in this study, after 1084 possible candidates were screened and 857 of them were excluded. The 227 participants presented with 237 lesions, and 10

1
2
3
4
5 participants showed breast lesions on both sides of the breasts. The whole procedure was shown in
6
7 figure 1. The age of the included participants ranged from 25 to 67 years. The results of pathological
8
9 examination showed that 159(67.1%) of the 237 lesions were benign and the other 78 (32.9%) were
10
11 malignant. The types of the benign and malignant lesions were shown in table 1. Two imaging
12
13 examples of an invasive ductal carcinoma diagnosed on both B-mode ultrasonography and
14
15 elastography were shown in figure2. Of all the 237 breast lesions, 191 (80.6%) were palpable
16
17 masses; 127 of them were benign and 64 were malignant. Sixty (25.3%) lesions were complained of
18
19 a history of bloody discharge; 7 of them were benign and 53 were malignant. The size of the lesions
20
21 ranged from 3.2mm to 38.7mm. The benign lesions showed a mean size of 8.16mm, while the
22
23 malignant lesions showed a mean size of 15.58mm. The agreement between the two radiologists
24
25 for ultrasound elastography was good ($\kappa=0.76$, $p<0.01$).

26 27 28 29 30 31 32 33 34 35 Predictors for SWE to detect malignant breast lesions

36
37 To evaluate whether elasticity scores, VTQ in the marginal area of the breast lesions (VTQm) and
38
39 VTQ in the central area of the breast lesions (VTQc) are potential predictors for detecting
40
41 malignancies in PND patients, a logistic regression was performed. The results showed that all of
42
43 the parameters were good predictors, malignant breast lesions illustrated a higher value of
44
45 elasticity score (malignant versus benign, 2.17 versus 3.51), VTQm (malignant versus benign, 2.54
46
47 m/s versus 3.39 m/s), and VTQc (malignant versus benign, 2.74 m/s versus 3.72 m/s). Table 2
48
49 showed the results of the logistic regression analysis, which showed a significant association
50
51 between higher values of elasticity score, VTQm and VTQc and higher possibility of malignant
52
53
54
55
56
57
58
59
60

breast lesions.

The diagnostic cut-off points of elasticity score, VTQm and VTQc

We calculated the cut-off points for elasticity scores, VTQm and VTQc. The results showed that a cut-off point of 2.50 for elasticity score yielded a sensitivity of 0.872(95%CI, 0.794 to 0.949), a specificity of 0.736 (95%CI, 0.667 to 0.805) and an area under the curve of 0.854. We also calculated a cut-off point of 3.285m/s for VTQm with a sensitivity of 0.615 (95%CI, 0.500 to 0.718), a specificity of 0.994(95%CI, 0.981 to 1.000) and an AUC of 0.826. Additionally, a cut-off point of 3.445 m/s was calculated for VTQc with a sensitivity of 0.628 (95%CI, 0.513 to 0.731), a specificity of 0.981 (95%CI, 0.956 to 1.000) and an AUC of 0.856. Figure 3 showed the details of each measurement.

Predictive value of a combination of measurements for elastography

We used a synthesized quantitative measurement to predict malignant breast lesions. The measurement categorized 168 (70.9%) breast lesions as benign and 69 (29.1%) as malignant.

The biopsy results showed that 159 (66.7%) breast lesions were classified as benign while 78 (33.3%) were malignant. We used the McNemar test to compare the synthesized measurement with the biopsy results, the result showed no significant difference (McNemar's chi-squared = 3.3684, $p=0.066$). The sensitivity, specificity, positive and negative predictive value (PPV and NPV) were 0.820, 0.968, 0.927 and 0.917, respectively. However, we compared elasticity score, VTQm and VTQc to the biopsy results respectively, using also the McNemar test. We found significant differences

1
2
3
4
5 between these quantitative results and the biopsy results ($p<0.01$). More details were shown in
6
7 table 3 and table 4.

9

10 11 12 Discussion

13
14 The results of our study showed that a combination of qualitative and quantitative measurements
15
16 for SWE elastography is highly sensitive and specific in predicting malignancy in PND patients, which
17
18 is consistent with several recent studies testing the diagnostic value of elastography in breast
19
20 masses[14 15 19]. However, several studies reported that ultrasonography was not predictive to
21
22 malignancy in PND patients[20-22]. We discussed our major findings and the remaining questions
23
24 below.
25
26
27

28
29 Predicting malignancy in patients with PND is still challenging, Sabel and colleagues found that 95%
30
31 of the PND lesions were benign, which need not be excised. However, most patients will choose
32
33 duct excision for palliative purposes[23]. In the screen phase of our study, 53 (5%) patients refuse to
34
35 take ductoscopy or duct excision and therefore were excluded. The patients refuse to take the
36
37 examinations for that no evidence of malignancy was found and they were afraid of the
38
39 contraindications of ductoscopy or duct excision. Based on these facts, a non-invasive method with
40
41 accurate diagnose are needed by patients with PND. Alcock found no predictive value of ductoscopy
42
43 and ultrasonography in differentiating benign and malignant breast lesions in PND patients. The
44
45 authors of this study suggested that ductal surgery was the only reliable way of providing a
46
47 diagnosis[24]. In our study, we found the PPV of the synthesized score for SWE elastography was
48
49 0.927. Moreover, our study showed a sensitivity of 0.820 and a specificity of 0.968 for SWE
50
51
52
53
54
55
56
57
58
59
60

1
2
3
4
5 elastography. This result indicated that SWE elastography could promote both the sensitivity and
6
7 specificity in ultrasonography examination, and therefore SWE elastography is of better diagnostic
8
9 performance than B-mode ultrasonography. So our study, for the first time, revealed that
10
11 ultrasonography elastography is valuable in predicting malignant lesions in patients with PND.
12
13 However, we should explain this result with caution. First, the incidence of malignancy among
14
15 patients with PND is high in our study. The incidence is 33.3%, while a reported incidence ranged
16
17 from 4% to 29%[25-28]. A higher incidence of malignancy may contribute to a higher positive
18
19 prediction, which may partly explain a high PPV found in our study.
20
21

22
23
24 The size of the breast mass could also be an important factor contributing to the high PPV. We
25
26 found that PND patients with malignant lesions presented a bigger size of the breast mass
27
28 (malignant versus benign, 15.58 mm versus 8.15 mm), which might be easier to be detected by
29
30 B-mode ultrasonography and elastography. This findings are consistent with other studies using
31
32 elastography to detect breast lesions[14 19]. On the other hand, this result indicated that PND
33
34 patients presented with no breast masses or the size of the breast masses below 8mm might not be
35
36 detected by elastography. So our study findings could only apply to PND patients with a breast
37
38 masses over 8mm large.
39
40

41
42
43 It is interesting to find out that 513 patients with PND refused to participate in our study. Absence
44
45 of these patients might contribute to a high incidence of malignant breast lesions, and thus made
46
47 the diagnostic value of elastography overestimated. The high rate of rejection could be caused by
48
49 the bad doctor-patient relationship in recent years in China[29]. Patients might go to several
50
51 doctors until they could accept the suggestions for further examination and treatment.
52
53
54
55
56
57
58
59
60

1
2
3
4
5 The synthesized score we used in this study is similar to a published method for classification of
6
7 benign and malignant breast lesions, except that we did not include the BI-RADS[14]. The BI-RADS is
8
9 a classification system, which is in part coincident with the elasticity score[17]. We chose elasticity
10
11 score instead of the BI-RADS into the synthesized score. The elasticity score is a qualitative
12
13 measurement, which was treated as continuous data in several studies[14 19 30]. We also treated
14
15 the elasticity score as a continuous data, so that we could calculate a cut-off point and include it
16
17 into the synthesized score. The way that we handled the elasticity score may bring bias into our
18
19 results. However, neither did we find a better way to solve the problem, nor did the previous
20
21 studies. Therefore, in future studies, a qualitative measurement should be developed, which
22
23 differentiate benign and malignant breast lesions more clearly than the elasticity score.
24
25
26
27
28

29
30 In this study, we incorporated both VTQ at the margin(VTQm) and in the center (VTQc) into the
31
32 synthesized score. To the best of our knowledge, we are the first to use these two quantitative
33
34 measurements, instead, previous studies normally used VTQc[7 14 19]. Inclusion of both VTQm and
35
36 VTQc could increase the understanding of the breast lesions, since they were reported to be
37
38 different[17 19]. The results of our study indicated that both VTQm and VTQc were significantly
39
40 higher in malignant lesions than benign ones. So we might have assigned more weight in the VTQ
41
42 measurement, and therefore made breast lesions with higher VTQ more easier to be malignant in
43
44 the synthesized score.
45
46
47
48

49
50 We have several limitations in this study. First, in the screening stage of our study, we excluded
51
52 patients without a positive ductoscopy findings, because we could not perform microdochectomy
53
54 without an exact location of the lesion reported by ductoscopy. However, ruling out these patients
55
56
57
58
59
60

1
2
3
4
5 may overestimated the diagnostic accuracy of elastography in PND patients. We followed-up these
6
7 patients to try to solve the problem in the future, but now we could not be definitive to what extent
8
9 we have exaggerated the diagnostic value of elastography. Second, the weight of elasticity score,
10
11 VTQm and VTQc were assigned evenly, and therefore made the value of VTQ a more important
12
13 factor than elasticity score in predicting malignancy in PND patients. Third, we used a
14
15 ductoscopy-guided microdochoectomy to get sample for biopsy. We might have missed the
16
17 malignant lesions, since ductoscopy could only reach a depth within 2cm[5]. The ideal way would
18
19 be that each patient was followed-up for at least 5 years to achieve a more definitive result.
20
21 However, now we still take the risk that we overestimate the PPV of elastography. Fourth, the
22
23 ultrasonography and elastography were obtained by one operator, which may induce bias to the
24
25 results, despite the operator was with 10 years' experience. Therefore, our study results should be
26
27 explained with caution.
28
29

30
31
32 In conclusion, ultrasonography elastography was predictive for malignancy in PND patients, with
33
34 breast mass over 8mm. However, the weight of the qualitative and quantitative measurements for
35
36 elastography warrants more studies.

Figure Legend

Figure 1 Flowchart of this study

Figure 2 The image of a 45-years old patient with invasive ductal carcinoma

The left picture showed a B-mode ultrasonography locating the region of interest (ROI). The right picture showed the elastography of the breast lesion, with the blue color indicated a harder tissue and the red color indicated a softer tissue.

Figure 3 The receiver-operating-characteristics (ROC) curve of Elasticity score, VTQ.m and VTQ.c.

The figure 3 showed the area under the curve (AUC), specificity, sensitivity and the best cut-off point of Elasticity score, VTQ.m and VTQ.c. for example the curves showed that Elasticity score yielded an AUC of 0.854, with a cut-off point of 2.50. At this cut-off point, the specificity was 0.736, while the sensitivity was 0.872. So we presented as 2.50(0.736, 0.872) in the figure.

Table 1 The distribution of benign and malignant lesions

Diagnosis after biopsy	Number of lesions (%)
Benign	159
Fibrocystic breast disease	82(51.6)
Fibroadenoma	60 (37.7)
Intraductal pailloma	6(3.8)
Atypical ductal hyperlasia	11(6.9)
Maglinant	78
Invasive ductal carcinoma	61(78.2)
Ductal carcinoma in situ	6(7.7)
Paillary carcinoma	7(9.0)

Table 4 BI-RADS classification and the synthesized measures

BI-RADS*	Elasticity score	VTQm	VTQc	Synthesized score	
	Mean(sd)	Mean(sd)	Mean(sd)	Benign(N, %)	Malignant(N, %)
3	1.98(0.64)	2.64(0.51)	2.86(0.55)	126(75.0)	13(18.8)
4A	2.84(0.68)	2.85(0.76)	3.02(0.76)	25(14.9)	12(17.4)
4B	3.91(0.29)	3.24(0.86)	3.48(0.78)	5(3.0)	17(24.6)
4C	3.71(0.61)	2.90(0.70)	3.34(0.84)	9(5.4)	5(7.2)
5	4.00(0.81)	3.31(0.62)	3.71(0.75)	3(1.8)	22(31.9)

Abbreviations: BI-RADS: the Breast Imaging Reporting and Data System. VTQm, virtual touch™ quantification at margin of a lesion. VTQc, virtual touch™ quantification at center of a lesion. SD, standardized deviation. N, number of counts.

* In the BI-RADS, 3 referred to probably benign, 4 referred to suspicious malignancy, 5 referred to highly suggestive of malignancy. In the 4 category, a subclassification was also used: (1) 4A: low suspicious for malignancy; (2) 4B: intermediate suspicious for malignancy; (3) 4C: moderate concern, but not classic for malignancy

STARD checklist for reporting of studies of diagnostic accuracy
(version January 2003)

Section and Topic	Item #		On page #
TITLE/ABSTRACT/ KEYWORDS	1	Identify the article as a study of diagnostic accuracy (recommend MeSH heading 'sensitivity and specificity').	1
INTRODUCTION	2	State the research questions or study aims, such as estimating diagnostic accuracy or comparing accuracy between tests or across participant groups.	5
METHODS			
<i>Participants</i>	3	The study population: The inclusion and exclusion criteria, setting and locations where data were collected.	5
	4	Participant recruitment: Was recruitment based on presenting symptoms, results from previous tests, or the fact that the participants had received the index tests or the reference standard?	5
	5	Participant sampling: Was the study population a consecutive series of participants defined by the selection criteria in item 3 and 4? If not, specify how participants were further selected.	Yes
	6	Data collection: Was data collection planned before the index test and reference standard were performed (prospective study) or after (retrospective study)?	5
<i>Test methods</i>	7	The reference standard and its rationale.	7-8
	8	Technical specifications of material and methods involved including how and when measurements were taken, and/or cite references for index tests and reference standard.	5-8
	9	Definition of and rationale for the units, cut-offs and/or categories of the results of the index tests and the reference standard.	5-8
	10	The number, training and expertise of the persons executing and reading the index tests and the reference standard.	6, 8
	11	Whether or not the readers of the index tests and reference standard were blind (masked) to the results of the other test and describe any other clinical information available to the readers.	6, 8
<i>Statistical methods</i>	12	Methods for calculating or comparing measures of diagnostic accuracy, and the statistical methods used to quantify uncertainty (e.g. 95% confidence intervals).	8-9
	13	Methods for calculating test reproducibility, if done.	9
RESULTS			
<i>Participants</i>	14	When study was performed, including beginning and end dates of recruitment.	9-10
	15	Clinical and demographic characteristics of the study population (at least information on age, gender, spectrum of presenting symptoms).	10
	16	The number of participants satisfying the criteria for inclusion who did or did not undergo the index tests and/or the reference standard; describe why participants failed to undergo either test (a flow diagram is strongly recommended).	10
<i>Test results</i>	17	Time-interval between the index tests and the reference standard, and any treatment administered in between.	10
	18	Distribution of severity of disease (define criteria) in those with the target condition; other diagnoses in participants without the target condition.	10
	19	A cross tabulation of the results of the index tests (including indeterminate and missing results) by the results of the reference standard; for continuous results, the distribution of the test results by the results of the reference standard.	10
	20	Any adverse events from performing the index tests or the reference standard.	10
<i>Estimates</i>	21	Estimates of diagnostic accuracy and measures of statistical uncertainty (e.g. 95% confidence intervals).	11-12
	22	How indeterminate results, missing data and outliers of the index tests were handled.	7, 11-12
	23	Estimates of variability of diagnostic accuracy between subgroups of participants, readers or centers, if done.	11-12
	24	Estimates of test reproducibility, if done.	11-12
DISCUSSION	25	Discuss the clinical applicability of the study findings.	12-13

ABSTRACT

Objectives: To test the diagnostic accuracy of shear wave elastography (SWE) in detecting malignancy in patients with pathological nipple discharge (PND).

Design: Prospective diagnostic accuracy study comparing a combination of qualitative and quantitative measurements of SWE (index test) to a ductoscopy and microdochectomy for histological diagnosis (reference test).

Setting: Fuzhou general hospital of Nanjing military command.

Participants: A total of 379 patients with PND were finally included from January, 2011 to March 2014, after we screened 1084 possible candidates. All participants were evaluated through a SWE with qualitative parameters generated by Virtual Touch™ tissue imaging (VTI) and quantitative parameters generated by Virtual Touch™ tissue quantification (VTQ). All the patients were consented to receive a ductoscopy and microdochectomy for histological diagnosis, and the results were set as a reference test.

Outcome measures: Sensitivity and specificity of the combined VTI and VTQ of the SWE for detection of malignancy in patients with PND.

Results: Results: The 379 participants presented with 404 lesions. The results of pathological examination showed that 326(80.7%) of the 404 lesions were benign and the other 78 (19.3%) were malignant. An area under the curve (AUC) of elasticity score, VTQm and VTQc were 0.872, 0.825, 0.857 respectively, with the corresponding cut-off point as 2.50, 2.860m/s and 3.015m/s respectively. After a combination of these measurements, the sensitivity, specificity, positive and negative predictive value (PPV and NPV) were 90.0%, 72.0%, 43.5% and 96.7%, respectively. The

sensitivity analysis showed a consistent result.

Conclusion: Ultrasonography elastography is sensitive for PND patients and could be used as a triage test before ductoscopy examination. A study for further improvement of diagnostic sensitivity is warranted by assigning proper weights to the qualitative and quantitative measurements for elastography.

Key words: Shear wave elastography; Pathological nipple discharge; Microdochoectomy; Breast Imaging- Reporting and Data System.

Strengths and limitations of this study

- Diagnostic accuracy of shear wave elastography (SWE) for detecting malignancy of PND patients is rarely studied.
- For the first time, this study tested diagnostic accuracy of a synthesized measurement of qualitative and quantitative measures of SWE for detection of malignancy in PND patients.
- Limitations include that the weight of each measurement in the synthesized score was assigned evenly and the surgeon was not blinded.

Introduction

In 2014, the American cancer society reported 235,030 new cases of breast cancer and 40,430 deaths because of it[1]. The prevalence rate of breast cancer is the highest in all types of malignant carcinoma in Chinese women [2]. The cases of Chinese women with breast cancer account for 12.2% of all newly diagnosed breast cancer around the world and 9.6% of deaths from breast cancer [2].

Pathological nipple discharge (PND) is the third most common complaint of patients prompting referral to doctors for breast diseases[3]. PND is believed to be an indicator for breast carcinoma, especially when the nipple discharge is bloody[3]. So mastectomies were carried out unnecessarily without obtaining a histopathological diagnosis before the year 1950. Although mastectomies are not necessarily needed nowadays, patients with PND would be normally suggested to take further examinations to rule out breast malignancy. These examinations involve mammography, ultrasonography, ductoscopy with or without galactography, as well as cytological tests. Mammography and B-mode ultrasonography are used for screening patients with high risk of breast carcinoma, but they are not sensitive enough for detecting malignancy in PND patients, since small lesions may be occult with these 2 modalities[4]. Ductoscopy and microdochectomy are the gold standard for diagnosis of malignancy in PND patients[5 6], but they are invasive examinations with high cost. Cytological tests could only be used as supportive evidence[7]. Therefore, a triage test is needed before the PND patients are suggested to take the ductoscopy and microdochectomy examination.

Ultrasonographic elastography works through the assumption that tissue compression produces strain within the tissue, and that the strain is smaller in firm tissue than in soft tissue. So we could

2
3
4
5 evaluate the firmness of the tissue to predict malignancy through measuring tissue strain ratio,
6
7 which is usually measured as elasticity[8]. Recently, several studies indicated that ultrasonographic
8
9 elastography may be a useful tool for differentiating benign and malignant masses. The sensitivity
10
11 of predicting malignancy in patients complaining breast lesions ranges from 80% to 98%, while the
12
13 specificity ranges from 66% to 84%[9-14]. Recently, a shear wave elastography (SWE) is reported to
14
15 be less operator-dependent and predictive of ductal or intraductal carcinoma[8 15 16]. A five-level
16
17 elasticity score is normally used for qualitative assessment of the images of elastography, while a
18
19 quantitative measurement of elastography is also becoming popular; a combination of these
20
21 ultrasonic measurements seems to be beneficial for improving diagnostic accuracy of breast
22
23 malignancies[8 16]. We noticed that the diagnostic value of SWE to detect malignancy in patients
24
25 with PND has rarely been studied, especially with a combination of qualitative and quantitative
26
27 measurements of SWE. So we conducted a study aiming to find out the sensitivity and specificity
28
29 accuracy of shear wave elastography (SWE) for predicting malignancy in patients with PND.

36 37 **Methods and materials**

38
39 This study is designed for evaluating diagnostic accuracy of shear wave elastography (SWE) for
40
41 detection of malignancy in patients with PND. The study protocol is approved by the ethical review
42
43 board in Fuzhou general hospital of Nanjing military command (No. FZJQ2011018), in which the
44
45 study was conducted and the data were collected. Data collection was planned before the index
46
47 and reference test.
48
49
50

51 52 *Patients*

53
54 Patients who complained of PND within 1 year were recruited from outpatient settings in the
55
56
57
58
59
60

Fuzhou general hospital of Nanjing military command. The PND was defined as nipple discharge in women who stopped breastfeeding and were not being pregnant[17]. The patients were screened for eligibility according to the following inclusion criteria: (1) with an age over 18 years; (2) with or without palpable breast masses; (3) agree to participate in this study; (4) providing a written consent for further examination, biopsy and use of the study data. We excluded the participants who (1) refused to receive a ductoscopy and microdochectomy or a biopsy; (2) had serious damage in internal organs that may bias the results; (3) could not receive local anesthesia because of allergy; (4) were taking or have taken chemotherapy or radiotherapy for malignant breast tumors.

Ultrasonographic imaging

The eligible participants were asked to take ultrasonographic examinations before receiving ductoscopy and microdochectomy. The ultrasonographic examinations included a B-mode ultrasound (BUS) and an elastography with acoustic radiation force Impulse (ARFI), which were performed with a Siemens ACUSON S2000 ultrasonographic system (Siemens Ltd., China, product standard: YZB/USA 3876-2010). One operator (with 10 years of experience in ultrasonography imaging) ran the BUS and the ARFI to get the BUS and elastography images, using a superficial probe (9L4, Siemens Ltd., China) with a frequency of 4 to 9 Hz.

The BUS images of the breast lesions were obtained and categorized according to Breast Imaging Reporting and Data System (BI-RADS). In the BI-RADS, number 1 refers to negative findings; number 2 refers to benign findings; number 3 refers to probably benign findings; number 4 refers to suspicious malignancy; number 5 is highly suggestive of malignancy. Moreover, we applied a subclassification scheme for BI-RADS 4: (1) 4A: low suspicious for malignancy; (2) 4B: intermediate

1
2
3
4 suspicious for malignancy; (3) 4C: moderate concern, but not classic for malignancy [18]. Two
5
6 radiologists (XBG and YL who are with at least 5 years of experience in ultrasonography)
7
8 independently assessed the BUS images in the following aspects: the shape of the mass, depth,
9
10 orientation, margin, boundary of the lesions, echo pattern, posterior acoustic features, as well as
11
12 surrounding tissue changes. All the detected masses were divided into two types (solid and cystic)
13
14 according to the presence of a cystic portion. In cases involving a solid mass in a dilated duct
15
16 (intraductal) or cyst (intracystic) with a predominant cystic portion, the radiologists considered the
17
18 cases as cystic type lesions.
19

20
21 After the BUS examination, the operator switched the ultrasonic mode to the virtual touch™
22
23 quantification (VTQ). The patients were told to hold the breath, when the operator detected the
24
25 inside and margin of the lesion, with a previous set region of interest (ROI) in a fixed region of
26
27 5×5cm. The operator recorded the value of VTQ (m/s) and the depth of the ROI (cm) from skin for
28
29 each measurement, in a total of 5 measurements. We calculated the mean value of the 5
30
31 measurements as the final VTQ score. Additionally, the value of VTQ was measured at both the
32
33 margin (VTQm) and center (VTQc) of the breast lesions. Measurable shear wave velocity (SWE)
34
35 ranges from 0 to 9 m/s, a value of ROI exceed the range would be shown as "X.XX m/s" on the
36
37 screen. The participants with this "X.XX m/s" value were excluded.
38
39

40
41 After finishing examination with the VTQ mode, the operators switched to virtual touch™ imaging
42
43 (VTI). ARFI sequences were generated to evaluate the elasticity scores of the breast lesions in VTI
44
45 mode. The VTI images were evaluated and categorized through a five-level scoring system[19]. An
46
47 elasticity score of 1 indicates strain in the entire hypoechoic lesion (the entire lesion is equally
48
49
50
51
52
53
54
55
56
57
58
59
60

shaded in green); score 2 indicates that strain is not seen in part of the hypoechoic lesion (the lesion is shown as a mosaic of green and blue); score 3 indicates that strain is in the peripheral areas only (peripheral areas in green); score 4 indicates no strain in the entire hypoechoic area (lesion is shown in blue); score 5 indicates no strain in the entire hypoechoic lesion or the surrounding area (both the entire hypoechoic lesion and its surrounding area are shown in blue). A higher elasticity score indicates a stiffer tissue. For cystic-type lesions, we analyzed the elasticity scores in solid areas. After the B-mode ultrasonography and ARFI elastography examination, 2 radiologists independently reviewed the images and the measurements without awareness of the medical history of the participants. Any discrepancy happened was solved by discussion.

Microdochectomy and pathological examination

After finishing the examination of BUS imaging and elastography, the participants received a ductoscopy examination. Microdochectomy was performed to get a biopsy sample if the ductoscopy indicated a breast lesion. The result of microdochectomy and pathological examination was set as a reference test (the golden standard). The patients were asked to stay in supine position with the arm preferably extending on a side board. After skin disinfection, the fluid-producing ducts were identified by massaging the breast towards the nipple. After dilating the target ducts with lacrimal dilators, a surgeon (with 5 years of experience in microdochectomy) introduced endoscope (a fiberoptic ductoscopy, 0.8mm of sheath, 80mm of length; manufactured in Denzlingen, Germany) through the ducts. The surgeon was not blinded from the results of the ultrasonographic examinations. After inserting the ductoscopy, the surgeon injected saline into the ducts to keep them expanded. The ductoscopy was advanced through the ducts under direct vision from the

1
2
3
4
5 endoscope camera, all tiers of branches were examined until the endoscope could not be advanced
6
7 further or an obstructing lesion was detected. When an obstructing lesion was found, the image of
8
9 this lesion would be taken using an endoscope camera, moreover, an endoscopy guided biopsy
10
11 would be performed as scheduled. After biopsy and image taken, the patient would be referred to a
12
13 surgeon for further treatment advice.
14
15

16
17 After detection of ductal lesions, methylene blue was injected into the discharged mammary duct.
18
19 Local anesthesia was performed and then an incision around the areola was implemented. The
20
21 pathological duct was separated according to tissue with methylene-blue stain, and the duct was
22
23 then dissected and excised. The operator then pulled the clip out of duct together with the scope
24
25 after the excision was finished. The biopsy samples over 1 mm³ were fixed using formalin after
26
27 sample collection and were sent for histologic examination.
28
29

30 31 32 *Statistical analysis* 33

34
35 Statistical analysis was performed to specify the diagnostic sensitivity and specificity of a
36
37 synthesized measurement of VTI (elasticity score) and VTQ measurements. First, we would assess
38
39 the interobserver variability between the two radiologists (XBG and YL) using the Cohen's kappa
40
41 test. The value of kappa over 0.75 was considered as excellent, 0.40 to 0.75 as fair to good, and
42
43 below 0.40 as poor. Second, we calculated the sensitivity, specificity and the area under the curve
44
45 (AUC) of elasticity score, VTQm and VTQc using receiver operating characteristics (ROC) curve. A
46
47 valued of AUC of 0.5 was considered as no diagnostic value; 0.5 to 0.7, low diagnostic value; 0.7 to
48
49 0.9, mediate diagnostic value; 0.9 to 1.0, high diagnostic value[20]. We calculated the cut-off point
50
51 of the elasticity score, VTQm and VTQc and gave the sensitivity and specificity respectively, based
52
53
54
55
56
57
58
59
60

on both the highest sum of sensitivity and specificity and a relatively high sensitivity of the measurements. According to the cut-off points, we synthesized the measurements by the following formula: the synthesized score=elasticity score + VTQm + VTQc. A synthesized score of 1 was given, if a value over the cut-off point was observed in a breast lesion; otherwise, a score of -1 was given. A breast lesion with a final score below 0 was classified as benign, otherwise it was categorized as malignant. Third, after differentiating benign and malignant lesions using the synthesized score, we evaluated the sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV). The diagnostic value of this synthesized measurement was compared with the biopsy results using the McNemar's test. We also compared the BI-RADS with the synthesized measurement using the chi-square test. All statistical analysis was performed using Statistical Package for the Social Sciences (SPSS, Version 20.0, Armonk, NY: IBM Corp.) and R software (www.r-project.org, version 3.1.1).

Results

A total of 379 patients with PND were included in this study, after 1084 possible candidates were screened and 705 of them were excluded. The 379 participants presented with 404 lesions, while 25 participants showed breast lesions on both sides. The process of eligibility screening and a brief description of the results of the BUS, elastography, ductoscopy and microdochoectomy examinations were shown in figure 1. The age of the included participants ranged from 25 to 67 years. The result of pathological examination showed that 326(80.7%) of the 404 lesions were benign and 78 (19.3%) were malignant. Table 1 shows the types of the benign and malignant lesions. Figure 2 and 3 show examples of invasive ductal carcinoma and fibroadenoma diagnosed with B-mode ultrasonography

and elastography. Of all the breast lesions, 191 (47.2%) were palpable masses; 127 of them were benign and 64 were malignant. A total of 59 participants complained of bloody discharge in 62 breast lesions(15.3%); 9 of them were benign and 53 were malignant. The size of the lesions ranged from 3.2mm to 38.7mm. The benign lesions showed a mean size of 8.16mm, while the malignant lesions showed a mean size of 15.58mm. Moderate or severe pain (with a score of visual analog scale over 50 mm) in the breast was reported by 133 of the 227 participants who received ductoscopy. Other adverse events were not reported. The agreement between the two radiologists for ultrasound elastography was good ($\kappa=0.76$, $p<0.01$).

The diagnostic cut-off points of the elasticity score, VTQm and VTQc

We calculated the cut-off points for elasticity scores, VTQm and VTQc. The results showed that a cut-off point of 2.50 for elasticity score yielded a sensitivity of 0.872(95%CI, 0.795 to 0.940), a specificity of 0.736 (95%CI, 0.660 to 0.805) and an area under the curve of 0.854. We also calculated a cut-off point of 2.860 m/s for VTQm with a sensitivity of 0.731 (95%CI, 0.628 to 0.821), a specificity of 0.742 (95%CI, 0.673 to 0.805) and an AUC of 0.825. Additionally, a cut-off point of 3.015 m/s was calculated for VTQc with a sensitivity of 0.731 (95%CI, 0.628 to 0.821), a specificity of 0.698 (95%CI, 0.616 to 0.761) and an AUC of 0.857. Table 2 showed raw numbers and diagnostic estimates of the elasticity score, VTQm and VTQc. Figure 4 shows the ROC curve of each measurement.

Diagnostic accuracy of a synthesized measurement of the elasticity score, VTQm and VTQc

We used a synthesized measurement of both quantitative and qualitative parameters to predict malignant breast lesions. The measurement categorized 243 (60.1%) breast lesions as benign and

1
2
3
4
5 161 (39.9%) as malignant. Table 3 shows a comparison of BI-RADS with the synthesized
6
7 measurement for elastography, and it showed that using BI-RADS diagnosed significantly less
8
9 participants with malignancy than the synthesized measurement (X-squared = 72.035, $p < 0.001$).

10
11
12 The biopsy results showed that 326 (80.6%) breast lesions were classified as benign while 78 (19.4%)
13
14 were malignant. We used the McNemar's test to compare the synthesized measurement with the
15
16 biopsy results, the result showed that significantly more malignant lesions were found by
17
18 elastography with the synthesized measurement (McNemar's chi-squared = 67.919, $p < 0.001$). The
19
20 sensitivity, specificity, positive and negative predictive value (PPV and NPV) were 0.900, 0.720,
21
22 0.435 and 0.967, respectively. Table 2 shows the raw numbers and diagnostic estimates of the
23
24 synthesized measurement. In the sensitivity analysis, we classified participants who were found
25
26 with no pathological changes by ductoscopy into a malignant category. The result showed that the
27
28 measurement of synthesized score categorized 212 (52.5%) breast lesions as benign and 192 (47.5%)
29
30 as malignant. The sensitivity and specificity were 0.949 and 0.638, respectively.

31 32 33 34 35 36 37 **Discussion**

38
39 The results of our study showed that a combination of qualitative and quantitative measurements
40
41 for SWE elastography is sensitive in predicting malignancy in PND patients, which is consistent with
42
43 several recent studies testing the diagnostic value of elastography in breast masses[8 16 21].
44
45 However, several studies reported that ultrasonography was not predictive to malignancy in PND
46
47 patients[22-24]. We discussed our major findings and the remaining questions below.

48
49 Predicting malignancy in patients with PND is still challenging, Sabel and colleagues found that 95%
50
51 of the PND lesions were benign, which need not be excised. However, most patients will choose
52
53
54
55
56
57
58
59
60

1
2
3
4
5 duct excision for palliative purposes[25]. In the screen phase of our study, 53 patients refuse to take
6
7 ductoscopy or duct excision and therefore were excluded. The patients refuse to take the
8
9 examinations for that no evidence of malignancy was found and they were afraid of the
10
11 contraindications of ductoscopy or duct excision. Therefore, a non-invasive method with accurate
12
13 diagnosis is needed by patients with PND. Alcock and Layer found no predictive value of ductoscopy
14
15 and ultrasonography in differentiating benign and malignant breast lesions in PND patients. The
16
17 authors of this study suggested that ductal surgery was the only reliable way of providing a
18
19 diagnosis[17]. In our study, we found the SWE elastography with a sensitivity of 90% for screening
20
21 malignancy in PND patients. This result indicated that SWE elastography could be used as a helpful
22
23 triage test before suggesting PND patients to ductoscopy examinations. And compared with
24
25 B-mode ultrasound, SWE elastography is with lower false negative risk, according to the comparison
26
27 of the BI-RADS and synthesized measurements in our study. And therefore SWE elastography is of
28
29 better diagnostic performance than B-mode ultrasonography. So our study, for the first time,
30
31 revealed that ultrasonographic elastography is valuable in predicting malignant lesions in patients
32
33 with PND.
34
35

36
37
38
39
40
41
42 The size of the breast mass might be an important factor in differentiating benign and malignant
43
44 lesions. We found that PND patients with malignant lesions presented a bigger size of the breast
45
46 mass (malignant versus benign, 15.58 mm versus 8.15 mm), which might be easier to be detected
47
48 by B-mode ultrasonography and elastography. This finding is consistent with other studies using
49
50 elastography to detect breast lesions[8 21]. However, whether the size of the breast mass could be
51
52 used as an independent indicator for predicting breast malignancy needs more studies.
53
54
55
56
57
58
59
60

1
2
3
4
5 The synthesized score we used in this study is similar to a published method for classification of
6
7 benign and malignant breast lesions, except that we did not include the BI-RADS[8]. The BI-RADS is
8
9 a classification system, which is in part coincident with the elasticity score[19]. We chose elasticity
10
11 score instead of the BI-RADS into the synthesized score. The elasticity score is a qualitative
12
13 measurement, which was treated as continuous data in several studies[8 21 26]. We also treated
14
15 the elasticity score as a continuous data, so that we could calculate a cut-off point and include it
16
17 into the synthesized score. The way that we handled the elasticity score may bring bias into our
18
19 results. However, neither did we find a better way to solve the problem, nor did the previous
20
21 studies. Therefore, in future studies, a qualitative measurement should be developed, which
22
23 differentiate benign and malignant breast lesions more clearly than the elasticity score.
24
25
26
27

28
29
30 In this study, we incorporated both VTQ at the margin (VTQm) and in the center (VTQc) into the
31
32 synthesized score. To the best of our knowledge, we are the first to use these two quantitative
33
34 measurements, instead, previous studies used VTQc alone[8 9 21]. Inclusion of both VTQm and
35
36 VTQc could increase the understanding of the breast lesions, since they were reported to be
37
38 different[19 21]. The results of our study indicated that both VTQm and VTQc were significantly
39
40 higher in malignant lesions than benign ones. So we might have assigned more weight in the VTQ
41
42 measurement, and therefore made breast lesions with higher VTQ more easier to be malignant in
43
44 the synthesized score.
45
46
47
48

49
50 We have several limitations in this study. First, a total of 152 participants were not found of
51
52 pathological change after ductoscopy examination, and thus were not performed microdochectomy
53
54 to get a biopsy result. These participants were classified as with benign lesions without solid
55
56
57
58
59
60

1
2
3
4
5 evidence. We might have missed the malignant lesions, since ductoscopy could only reach a depth
6
7 within 2cm[5]. To ensure the reliability of our study, we ran a sensitivity analysis, in which all these
8
9 participants were classified as with malignant lesions. And we found the result was consistent.
10
11 Moreover, we found that the incidence of malignancy in PND patients is 19.3% in our study, while a
12
13 reported incidence ranged from 4% to 29%[26-29]. This supported that the 152 participants were
14
15 classified as with benign lesions. Second, the weight of elasticity score, VTQm and VTQc were
16
17 assigned evenly, and therefore made the value of VTQ a more important factor than elasticity score
18
19 in predicting malignancy in PND patients. Third, the surgeon who performed the ductoscopy was
20
21 not blinded from the ultrasonographic results, which may introduce performance bias.
22
23
24
25
26

27 In conclusion, ultrasonography elastography is sensitive for PND patients and could be considered
28
29 as a triage test before ductoscopy examination. However, a study for further improvement of
30
31 diagnostic sensitivity is warranted by assigning proper weights to the qualitative and quantitative
32
33 measurements for elastography.
34

Figure Legend

Figure 1. Flowchart of this study

* We used the Breast Imaging Reporting and Data System (BI-RADS) to classified the breast lesions in B-mode ultrasound. In the BI-RADS, number 3 refers to probably benign, number 4 refers to suspicious malignancy, number 5 refers to highly suggestive of malignancy. In the level 4 category, a subclassification is used: (1) 4A: low suspicious for malignancy; (2) 4B: intermediate suspicious for malignancy; (3) 4C: moderate concern, but not classic for malignancy.

Figure 2. The image of a 45-years old patient with invasive ductal carcinoma

The left picture shows a B-mode ultrasonography locating the region of interest (ROI). The right picture shows the elastography of the breast lesion, with the blue color indicates a harder tissue and the red color indicated a softer tissue.

Figure 3. The image of a 41-years old patient with fibroadenoma

A B-mode ultrasonography at the left of the picture shows a location of the region of interest (ROI). An elastography picture at the right shows the elasticity of the fibroadenoma.

Figure 4. The receiver-operating-characteristics (ROC) curve of elasticity score, VTQm and VTQc

VTQm, virtual touch™ quantification at margin of a lesion. VTQc, virtual touch™ quantification at center of a lesion. The figure shows the area under the curve (AUC), specificity and sensitivity of Elasticity score, VTQm and VTQc. A cut-off point of 2.50 was selected for elasticity score yielding a sensitivity of 0.872 (95%CI, 0.795 to 0.940), a specificity of 0.736 (95%CI, 0.660 to 0.805) and an area under the curve of 0.854. A cut-off point of 2.860 m/s was selected for VTQm yielding a sensitivity of 0.731 (95%CI, 0.628 to 0.821), a specificity of 0.742 (95%CI, 0.673 to 0.805) and an AUC of 0.825. Additionally, a cut-off point of

STARD checklist for reporting of studies of diagnostic accuracy
(version January 2003)

Section and Topic	Item #		On page #
TITLE/ABSTRACT/ KEYWORDS	1	Identify the article as a study of diagnostic accuracy (recommend MeSH heading 'sensitivity and specificity').	1
INTRODUCTION	2	State the research questions or study aims, such as estimating diagnostic accuracy or comparing accuracy between tests or across participant groups.	5
METHODS			
<i>Participants</i>	3	The study population: The inclusion and exclusion criteria, setting and locations where data were collected.	5
	4	Participant recruitment: Was recruitment based on presenting symptoms, results from previous tests, or the fact that the participants had received the index tests or the reference standard?	5
	5	Participant sampling: Was the study population a consecutive series of participants defined by the selection criteria in item 3 and 4? If not, specify how participants were further selected.	Yes
	6	Data collection: Was data collection planned before the index test and reference standard were performed (prospective study) or after (retrospective study)?	5
<i>Test methods</i>	7	The reference standard and its rationale.	5
	8	Technical specifications of material and methods involved including how and when measurements were taken, and/or cite references for index tests and reference standard.	5-8
	9	Definition of and rationale for the units, cut-offs and/or categories of the results of the index tests and the reference standard.	5-8
	10	The number, training and expertise of the persons executing and reading the index tests and the reference standard.	6, 8
	11	Whether or not the readers of the index tests and reference standard were blind (masked) to the results of the other test and describe any other clinical information available to the readers.	6, 8
<i>Statistical methods</i>	12	Methods for calculating or comparing measures of diagnostic accuracy, and the statistical methods used to quantify uncertainty (e.g. 95% confidence intervals).	9-10
	13	Methods for calculating test reproducibility, if done.	9
RESULTS			
<i>Participants</i>	14	When study was performed, including beginning and end dates of recruitment.	10
	15	Clinical and demographic characteristics of the study population (at least information on age, gender, spectrum of presenting symptoms).	10
	16	The number of participants satisfying the criteria for inclusion who did or did not undergo the index tests and/or the reference standard; describe why participants failed to undergo either test (a flow diagram is strongly recommended).	10, figure 1
<i>Test results</i>	17	Time-interval between the index tests and the reference standard, and any treatment administered in between.	10
	18	Distribution of severity of disease (define criteria) in those with the target condition; other diagnoses in participants without the target condition.	10
	19	A cross tabulation of the results of the index tests (including indeterminate and missing results) by the results of the reference standard; for continuous results, the distribution of the test results by the results of the reference standard.	10, table 2
	20	Any adverse events from performing the index tests or the reference standard.	10
<i>Estimates</i>	21	Estimates of diagnostic accuracy and measures of statistical uncertainty (e.g. 95% confidence intervals).	11-12, table 2
	22	How indeterminate results, missing data and outliers of the index tests were handled.	7, 11-12
	23	Estimates of variability of diagnostic accuracy between subgroups of participants, readers or centers, if done.	No
	24	Estimates of test reproducibility, if done.	No
DISCUSSION	25	Discuss the clinical applicability of the study findings.	12-13

ABSTRACT

Objectives: Pathological nipple discharge (PND) may indicate malignant breast lesions, the role of shear wave elastography (SWE) in predicting these malignant lesions were not evaluated. We aim to evaluate the diagnostic value of SWE for this condition.

Design: Prospective diagnostic accuracy study comparing a combination of qualitative and quantitative measurements of SWE (index test) to a ductoscopy and microdochoectomy for histological diagnosis (reference test).

Setting: Fuzhou general hospital of Nanjing military command.

Participants: A total of 379 patients with PND were finally included from January, 2011 to March 2014, after we screened 1084 possible candidates. All participants were evaluated through a SWE with qualitative parameters generated by Virtual Touch™ tissue imaging (VTI) and quantitative parameters generated by Virtual Touch™ tissue quantification (VTQ). All the patients were consented to receive a ductoscopy and microdochoectomy for histological diagnosis, and the results were set as a reference test.

Outcome measures: Sensitivity and specificity of the combined VTI and VTQ of the SWE for detection of malignancy in patients with PND.

Results: The 379 participants presented with 404 lesions. The results of pathological examination showed that 326(80.7%) of the 404 lesions were benign and the other 78 (19.3%) were malignant. An area under the curve (AUC) of elasticity score, VTQm and VTQc were 0.872, 0.825, 0.857 respectively, with the corresponding cut-off point as 2.50, 2.860m/s and 3.015m/s respectively. After a combination of these measurements, the sensitivity, specificity, positive and negative predictive value (PPV and NPV) were 89.7%, 72.1%, 43.5% and 96.7%, respectively. The sensitivity

analysis showed 82.0% of the sensitivity and 96.8% of the specificity, in which patients with no pathological findings in ductoscopy were excluded.

Conclusion: Ultrasonography elastography is sensitive for PND patients and could be used as a triage test before ductoscopy examination. Studies for further improvement of diagnostic sensitivity are warranted.

Key words: Shear wave elastography; Pathological nipple discharge; Microdochectomy; Breast Imaging- Reporting and Data System.

Strengths and limitations of this study

- Diagnostic accuracy of shear wave elastography (SWE) for detecting malignancy of PND patients is rarely studied.
- For the first time, this study tested diagnostic accuracy of a synthesized measurement of qualitative and quantitative measures of SWE for detection of malignancy in PND patients.
- Limitations include that the weight of each measurement in the synthesized score was assigned evenly and the surgeon was not blinded.

Introduction

In 2014, the American cancer society reported 235,030 new cases of breast cancer and 40,430 deaths because of it[1]. The prevalence rate of breast cancer is the highest in all types of malignant carcinoma in Chinese women [2]. The cases of Chinese women with breast cancer account for 12.2% of all newly diagnosed breast cancer around the world and 9.6% of deaths from breast cancer [2].

Pathological nipple discharge (PND) is the third most common complaint of patients prompting referral to doctors for breast diseases[3]. PND is believed to be an indicator for breast carcinoma, especially when the nipple discharge is bloody[3]. So mastectomies were carried out unnecessarily without obtaining a histopathological diagnosis before the year 1950. Although mastectomies are not necessarily needed nowadays, patients with PND would be normally suggested to take further examinations to rule out breast malignancy. These examinations involve mammography, ultrasonography, ductoscopy with or without galactography, as well as cytological tests. Mammography and B-mode ultrasonography are used for screening patients with high risk of breast carcinoma, but they are not sensitive enough for detecting malignancy in PND patients, since small lesions may be occult with these 2 modalities[4]. Ductoscopy and microdochectomy are the gold standard for diagnosis of malignancy in PND patients[5 6]. In clinical practice patients with PND will conventionally be suggested for a ductoscopy, but ductoscopy and microdochectomy are invasive examinations with high cost, so some patients will refuse ductoscopy and turn to other non-invasive tests instead. Cytological tests could only be used as supportive evidence[7]. Therefore, a triage test is needed before the PND patients are suggested to take the ductoscopy and microdochectomy examination.

Ultrasonographic elastography works through the assumption that tissue compression produces strain within the tissue, and that the strain is smaller in firm tissue than in soft tissue. So we could evaluate the firmness of the tissue to predict malignancy through measuring tissue strain ratio, which is usually measured as elasticity[8]. Recently, several studies indicated that ultrasonographic elastography may be a useful tool for differentiating benign and malignant masses. The sensitivity of predicting malignancy in patients complaining breast lesions ranges from 80% to 98%, while the specificity ranges from 66% to 84%[9-14]. Recently, a shear wave elastography (SWE) is reported to be less operator-dependent and predictive of ductal or intraductal carcinoma[8 15 16]. A five-level elasticity score is normally used for qualitative assessment of the images of elastography, while a quantitative measurement of elastography is also becoming popular; a combination of these ultrasonic measurements seems to be beneficial for improving diagnostic accuracy of breast malignancies[8 16]. We noticed that the diagnostic value of SWE to detect malignancy in patients with PND has rarely been studied, especially with a combination of qualitative and quantitative measurements of SWE. So we conducted a study aiming to find out the sensitivity and specificity accuracy of shear wave elastography (SWE) for predicting malignancy in patients with PND.

Methods and materials

This study is designed for evaluating diagnostic accuracy of shear wave elastography (SWE) for detection of malignancy in patients with PND. The study protocol is approved by the ethical review board in Fuzhou general hospital of Nanjing military command (No. FZJQ2011018), in which the study was conducted and the data were collected. Data collection was planned before the index and reference test.

Patients

Patients with PND symptoms less than a year duration were recruited from outpatient settings in the Fuzhou general hospital of Nanjing military command. The PND was defined as nipple discharge in women who stopped breastfeeding and were not being pregnant[17]. The patients were screened for eligibility according to the following inclusion criteria: (1) with an age over 18 years; (2) with or without palpable breast masses; (3) agree to participate in this study; (4) providing a written consent for further examination, biopsy and use of the study data. We excluded the participants who (1) refused to receive a ductoscopy and microdocheotomy or a biopsy; (2) had serious damage in internal organs that may bias the results; (3) could not receive local anesthesia because of allergy; (4) were taking or have taken chemotherapy or radiotherapy for malignant breast tumors.

Ultrasonographic imaging

The eligible participants were asked to take ultrasonographic examinations before receiving ductoscopy and microdocheotomy. The ultrasonographic examinations included a B-mode ultrasound (BUS) and an elastography with acoustic radiation force Impulse (ARFI), which were performed with a Siemens ACUSON S2000 ultrasonographic system (Siemens Ltd., China, product standard: YZB/USA 3876-2010). One operator (with 10 years of experience in ultrasonography imaging) ran the BUS and the ARFI to get the BUS and elastography images, using a superficial probe (9L4, Siemens Ltd., China) with a frequency of 4 to 9 Hz.

The BUS images of the breast lesions were obtained and categorized according to Breast Imaging Reporting and Data System (BI-RADS). In the BI-RADS, number 1 refers to negative findings; number 2 refers to benign findings; number 3 refers to probably benign findings; number 4 refers

1
2
3
4 to suspicious malignancy; number 5 is highly suggestive of malignancy. Moreover, we applied a
5
6 subclassification scheme for BI-RADS 4: (1) 4A: low suspicious for malignancy; (2) 4B:
7
8 intermediate suspicious for malignancy; (3) 4C: moderate concern, but not classic for malignancy
9
10
11 [18]. Two radiologists (XBG and YL who are with at least 5 years of experience in ultrasonography)
12
13
14 independently assessed the BUS images in the following aspects: the shape of the mass, depth,
15
16 orientation, margin, boundary of the lesions, echo pattern, posterior acoustic features, as well as
17
18 surrounding tissue changes. All the detected masses were divided into two types (solid and cystic)
19
20 according to the presence of a cystic portion. In cases involving a solid mass in a dilated duct
21
22 (intraductal) or cyst (intracystic) with a predominant cystic portion, the radiologists considered
23
24 the cases as cystic type lesions.
25
26
27

28
29 After the BUS examination, the operator switched the ultrasonic mode to the virtual touch™
30
31 quantification (VTQ). The patients were told to hold the breath, when the operator detected the
32
33 inside and margin of the lesion, with a previous set region of interest (ROI) in a fixed region of
34
35 5×5cm. The operator recorded the value of VTQ (m/s) and the depth of the ROI (cm) from skin for
36
37 each measurement, in a total of 5 measurements. We calculated the mean value of the 5
38
39 measurements as the final VTQ score. Additionally, the value of VTQ was measured at both the
40
41 margin (VTQm) and center (VTQc) of the breast lesions. Measurable shear wave velocity (SWE)
42
43 ranges from 0 to 9 m/s, a value of ROI exceed the range would be shown as "X.XX m/s" on the
44
45 screen. The participants with this "X.XX m/s" value were excluded.
46
47
48

49
50 After finishing examination with the VTQ mode, the operators switched to virtual touch™
51
52 imaging (VTI). ARFI sequences were generated to evaluate the elasticity scores of the breast
53
54 lesions in VTI mode. The VTI images were evaluated and categorized through a five-level scoring

system[19]. An elasticity score of 1 indicates strain in the entire hypoechoic lesion (the entire lesion is equally shaded in green); score 2 indicates that strain is not seen in part of the hypoechoic lesion (the lesion is shown as a mosaic of green and blue); score 3 indicates that strain is in the peripheral areas only (peripheral areas in green); score 4 indicates no strain in the entire hypoechoic area (lesion is shown in blue); score 5 indicates no strain in the entire hypoechoic lesion or the surrounding area (both the entire hypoechoic lesion and its surrounding area are shown in blue). A higher elasticity score indicates a stiffer tissue. For cystic-type lesions, we analyzed the elasticity scores in solid areas. After the B-mode ultrasonography and ARFI elastography examination, 2 radiologists independently reviewed the images and the measurements without awareness of the medical history of the participants. Any discrepancy happened was solved by discussion.

31 *Microdochoectomy and pathological examination*

32

After finishing the examination of BUS imaging and elastography, the participants received a ductoscopy examination. Microdochoectomy was performed to get a biopsy sample if the ductoscopy indicated a breast lesion. The result of microdochoectomy and pathological examination was set as a reference test (the golden standard). The patients were asked to stay in supine position with the arm preferably extending on a side board. After skin disinfection, the fluid-producing ducts were identified by massaging the breast towards the nipple. After dilating the target ducts with lacrimal dilators, a surgeon (with 5 years of experience in microdochoectomy) introduced endoscope (a fiberoptic ductoscopy, 0.8mm of sheath, 80mm of length; manufactured in Denzlingen, Germany) through the ducts. The surgeon was not blinded from the results of the ultrasonographic examinations. After inserting the ductoscopy, the surgeon injected

1
2
3
4 saline into the ducts to keep them expanded. The ductoscopy was advanced through the ducts
5
6 under direct vision from the endoscope camera, all tiers of branches were examined until the
7
8 endoscope could not be advanced further or an obstructing lesion was detected. When an
9
10 obstructing lesion was found, the image of this lesion would be taken using an endoscope camera,
11
12 moreover, an endoscopy guided biopsy would be performed as scheduled. After biopsy and
13
14 image taken, the patient would be referred to a surgeon for further treatment advice.
15
16

17
18 After detection of ductal lesions, methylene blue was injected into the discharged mammary duct.
19
20 Local anesthesia was performed and then an incision around the areola was implemented. The
21
22 pathological duct was separated according to tissue with methylene-blue stain, and the duct was
23
24 then dissected and excised. The operator then pulled the clip out of duct together with the scope
25
26 after the excision was finished. The biopsy samples over 1 mm³ were fixed using formalin after
27
28 sample collection and were sent for histologic examination.
29
30
31
32

33 34 *Statistical analysis*

35
36 Statistical analysis was performed to specify the diagnostic sensitivity and specificity of a
37
38 synthesized measurement of VTl (elasticity score) and VTQ measurements. First, we would assess
39
40 the interobserver variability between the two radiologists (XBG and YL) using the Cohen's kappa
41
42 test. The value of kappa over 0.75 was considered as excellent, 0.40 to 0.75 as fair to good, and
43
44 below 0.40 as poor. Second, we calculated the sensitivity, specificity and the area under the curve
45
46 (AUC) of elasticity score, VTQm and VTQc using receiver operating characteristics (ROC) curve. A
47
48 valued of AUC of 0.5 was considered as no diagnostic value; 0.5 to 0.7, low diagnostic value; 0.7
49
50 to 0.9, mediate diagnostic value; 0.9 to 1.0, high diagnostic value[20]. We calculated the cut-off
51
52 point of the elasticity score, VTQm and VTQc and gave the sensitivity and specificity respectively,
53
54
55
56
57
58
59
60

1
2
3
4 based on both the highest sum of sensitivity and specificity and a relatively high sensitivity of the
5
6 measurements. According to the cut-off points, we synthesized the measurements by the
7
8 following formula: the synthesized score=elasticity score + VTQm + VTQc. A synthesized score of 1
9
10 was given, if a value over the cut-off point was observed in a breast lesion; otherwise, a score of
11
12 -1 was be given. A breast lesion with a final score below 0 was classified as benign, otherwise it
13
14 was categorized as malignant. Third, after differentiating benign and malignant lesions using the
15
16 synthesized score, we evaluated the sensitivity, specificity, positive predictive value (PPV) and
17
18 negative predictive value (NPV). The diagnostic value of this synthesized measurement was
19
20 compared with the biopsy results using the McNemar's test. We also compared the BI-RADS with
21
22 the synthesized measurement using the chi-square test. All statistical analysis was performed
23
24 using Statistical Package for the Social Sciences (SPSS, Version 20.0, Armonk, NY: IBM Corp.) and R
25
26 software (www.r-project.org, version 3.1.1).

32

33 34 **Results**

35
36 A total of 379 patients with PND were included in this study, after 1084 possible candidates were
37
38 screened and 705 of them were excluded. The 379 participants presented with 404 lesions, while
39
40 25 participants showed breast lesions on both sides. The process of eligibility screening and a
41
42 brief description of the results of the BUS, elastography, ductoscopy and microdochectomy
43
44 examinations were shown in figure 1. The age of the included participants ranged from 25 to 67
45
46 years. The result of pathological examination showed that 326(80.7%) of the 404 lesions were
47
48 benign and 78 (19.3%) were malignant. Table 1 shows the types of the benign and malignant
49
50 lesions. Figure 2 and 3 show examples of invasive ductal carcinoma and fibroadenoma diagnosed
51
52 with B-mode ultrasonography and elastography. Of all the breast lesions, 191 (47.2%) were
53
54
55
56
57
58
59
60

1
2
3
4 palpable masses; 127 of them were benign and 64 were malignant. A total of 59 participants
5
6 complained of bloody discharge in 62 breast lesions(15.3%); 9 of them were benign and 53 were
7
8 malignant. The size of the lesions ranged from 3.2mm to 38.7mm. The benign lesions showed a
9
10 mean size of 8.16mm, while the malignant lesions showed a mean size of 15.58mm. No patients
11
12 with SWE exceeding the range were found. Moderate or severe pain (with a score of visual
13
14 analog scale over 50 mm) in the breast was reported by 133 of the 227 participants who received
15
16 ductoscopy. Other adverse events were not reported. The agreement between the two
17
18 radiologists for ultrasound elastography was good ($\kappa=0.76$, $p<0.01$).

19 20 21 22 23 24 *The diagnostic cut-off points of the elasticity score, VTQm and VTQc*

25
26 We calculated the cut-off points for elasticity scores, VTQm and VTQc. The results showed that a
27
28 cut-off point of 2.50 for elasticity score yielded a sensitivity of 0.872(95%CI, 0.795 to 0.940), a
29
30 specificity of 0.736 (95%CI, 0.660 to 0.805) and an area under the curve of 0.854. We also
31
32 calculated a cut-off point of 2.860 m/s for VTQm with a sensitivity of 0.731 (95%CI, 0.628 to
33
34 0.821), a specificity of 0.742 (95%CI, 0.673 to 0.805) and an AUC of 0.825. Additionally, a cut-off
35
36 point of 3.015 m/s was calculated for VTQc with a sensitivity of 0.731 (95%CI, 0.628 to 0.821), a
37
38 specificity of 0.698 (95%CI, 0.616 to 0.761) and an AUC of 0.857. Table 2 showed raw numbers
39
40 and diagnostic estimates of the elasticity score, VTQm and VTQc. Figure 4 shows the ROC curve of
41
42 each measurement.
43
44
45
46
47

48 49 50 51 52 *Diagnostic accuracy of a synthesized measurement of the elasticity score, VTQm and VTQc*

53
54 We used a synthesized measurement of both quantitative and qualitative parameters to predict
55
56 malignant breast lesions. The measurement categorized 243 (60.1%) breast lesions as benign and
57
58 161 (39.9%) as malignant. Table 3 shows a comparison of BI-RADS with the synthesized
59
60

1
2
3
4 measurement for elastography, and it showed that using BI-RADS diagnosed significantly less
5
6 participants with malignancy than the synthesized measurement (X-squared = 72.035, $p < 0.001$).
7

8
9 The biopsy results showed that 326 (80.6%) breast lesions were classified as benign while 78
10
11 (19.4%) were malignant. We used the McNemar's test to compare the synthesized measurement
12
13 with the biopsy results, the result showed that significantly more malignant lesions were found
14
15 by elastography with the synthesized measurement (McNemar's chi-squared = 67.919, $p < 0.001$).
16
17

18 The sensitivity, specificity, positive and negative predictive value (PPV and NPV) were 0.897,
19
20 0.721, 0.435 and 0.967, respectively. Table 2 shows the raw numbers and diagnostic estimates of
21
22 the synthesized measurement. In the sensitivity analysis, we excluded 152 participants who were
23
24 found with no pathological changes by ductoscopy and included 227 participants. These
25
26 participants presented with 237 breast lesions. The measurement of synthesized score
27
28 categorized 168 (70.9%) breast lesions as benign and 69 (29.1%) as malignant. Results of the
29
30 reference test showed that 159(67.1%) of the 237 lesions were benign and the other 78 (32.9%)
31
32 were malignant. The sensitivity and specificity were 0.820 and 0.968, respectively.
33
34
35
36
37
38

39 Discussion

40
41 The results of our study showed that a combination of qualitative and quantitative
42
43 measurements for SWE elastography is sensitive in predicting malignancy in PND patients, which
44
45 is consistent with several recent studies testing the diagnostic value of elastography in breast
46
47 masses[8 16 21]. However, several studies reported that ultrasonography was not predictive to
48
49 malignancy in PND patients[22-24]. We discussed our major findings and the remaining questions
50
51 below.
52
53
54

55
56 Predicting malignancy in patients with PND is still challenging, Sabel and colleagues found that 95%
57
58
59
60

1
2
3
4 of the PND lesions were benign, which need not be excised. However, most patients will choose
5
6 duct excision for palliative purposes[25]. In the screen phase of our study, 53 patients refuse to
7
8 take ductoscopy or duct excision and therefore were excluded. The patients refuse to take the
9
10 examinations for that no evidence of malignancy was found and they were afraid of the
11
12 contraindications of ductoscopy or duct excision. Therefore, a non-invasive method with accurate
13
14 diagnosis is needed by patients with PND. Alcock and Layer found no predictive value of
15
16 ductoscopy and ultrasonography in differentiating benign and malignant breast lesions in PND
17
18 patients. The authors of this study suggested that ductal surgery was the only reliable way of
19
20 providing a diagnosis[17]. In our study, we found the SWE elastography with a sensitivity of 90%
21
22 for screening malignancy in PND patients. This result indicated that SWE elastography could be
23
24 used as a helpful triage test before suggesting PND patients to ductoscopy examinations. And
25
26 compared with B-mode ultrasound, SWE elastography is with lower false negative risk, according
27
28 to the comparison of the BI-RADS and synthesized measurements in our study. And therefore
29
30 SWE elastography is of better diagnostic performance than B-mode ultrasonography. So our study,
31
32 for the first time, revealed that ultrasonographic elastography is valuable in predicting malignant
33
34 lesions in patients with PND.
35
36
37
38
39
40
41
42

43
44 The size of the breast mass might be an important factor in differentiating benign and malignant
45
46 lesions. We found that PND patients with malignant lesions presented a bigger size of the breast
47
48 mass (malignant versus benign, 15.58 mm versus 8.15 mm), which might be easier to be detected
49
50 by B-mode ultrasonography and elastography. This finding is consistent with other studies using
51
52 elastography to detect breast lesions[8 21]. However, whether the size of the breast mass could
53
54 be used as an independent indicator for predicting breast malignancy needs more studies.
55
56
57
58
59
60

1
2
3
4 It is interesting to find out that 513 patients with PND refused to take ductoscopy examination in
5
6 our study. Absence of these patients might contribute to a high incidence of malignant breast
7
8 lesions, and thus made the diagnostic value of elastography overestimated. The reason may be
9
10 that patients with PND worried about post-operative pain and procedure cost, so they turned to
11
12 other non-invasive tests. When the non-invasive tests showed no positive findings, they would
13
14 refuse to take ductoscopy, which is the reason that we carried out this study to find out a reliable
15
16 and pain-free test for them.
17
18
19

20
21 The synthesized score we used in this study is similar to a published method for classification of
22
23 benign and malignant breast lesions, except that we did not include the BI-RADS[8]. The BI-RADS
24
25 is a classification system, which is in part coincident with the elasticity score[19]. We chose
26
27 elasticity score instead of the BI-RADS into the synthesized score. The elasticity score is a
28
29 qualitative measurement, which was treated as continuous data in several studies[8 21 26]. We
30
31 also treated the elasticity score as a continuous data, so that we could calculate a cut-off point
32
33 and include it into the synthesized score. The way that we handled the elasticity score may bring
34
35 bias into our results. However, neither did we find a better way to solve the problem, nor did the
36
37 previous studies. Therefore, in future studies, a qualitative measurement should be developed,
38
39 which differentiate benign and malignant breast lesions more clearly than the elasticity score.
40
41
42
43
44

45
46 In this study, we incorporated both VTQ at the margin (VTQm) and in the center (VTQc) into the
47
48 synthesized score. To the best of our knowledge, we are the first to use these two quantitative
49
50 measurements, instead, previous studies used VTQc alone[8 9 21]. Inclusion of both VTQm and
51
52 VTQc could increase the understanding of the breast lesions, since they were reported to be
53
54 different[19 21]. The results of our study indicated that both VTQm and VTQc were significantly
55
56
57
58
59
60

1
2
3
4 higher in malignant lesions than benign ones. So we might have assigned more weight in the VTQ
5
6 measurement, and therefore made breast lesions with higher VTQ easier to be malignant in the
7
8 synthesized score.
9

10
11 We have several limitations in this study. First, a total of 152 participants were not found of
12
13 pathological change after ductoscopy examination, and thus were not performed
14
15 microdochoectomy to get a biopsy result. These participants were classified as with benign lesions
16
17 without solid evidence. We might have missed the malignant lesions, since ductoscopy could only
18
19 reach a depth within 2cm[5]. To ensure the reliability of our study, we ran a sensitivity analysis, in
20
21 which all these participants were classified as with malignant lesions. And we found the result
22
23 was consistent. Moreover, we found that the incidence of malignancy in PND patients is 19.3% in
24
25 our study, while a reported incidence ranged from 4% to 29%[27-30]. This supported that the 152
26
27 participants were classified as with benign lesions. Second, the weight of elasticity score, VTQm
28
29 and VTQc were assigned evenly, and therefore made the value of VTQ a more important factor
30
31 than elasticity score in predicting malignancy in PND patients. Third, the surgeon who performed
32
33 the ductoscopy was not blinded from the ultrasonographic results, which may introduce
34
35 performance bias.
36
37
38
39
40
41
42

43
44 In conclusion, ultrasonography elastography is sensitive for PND patients and could be considered
45
46 as a triage test before ductoscopy examination. However, a study for further improvement of
47
48 diagnostic sensitivity is warranted by assigning proper weights to the qualitative and quantitative
49
50 measurements for elastography.
51

Figure Legend

Figure 1. Flowchart of this study

* There were 379 participants presenting 404 lesions. In the results, we count the number of lesions instead of the patients. The index test is shear wave elastography on the basis of B-mode ultrasound. The reference test is ductoscopy and subsequent microdochectomy if pathological changes was found in ductoscopy.

Figure 2. The image of a 45-years old patient with invasive ductal carcinoma

The left picture shows a B-mode ultrasonography locating the region of interest (ROI). The right picture shows the elastography of the breast lesion, with the blue color indicates a harder tissue and the red color indicated a softer tissue.

Figure 3. The image of a 41-years old patient with fibroadenoma

A B-mode ultrasonography at the left of the picture shows a location of the region of interest (ROI). An elastography picture at the right shows the elasticity of the fibroadenoma.

Figure 4. The receiver-operating-characteristics (ROC) curve of elasticity score, VTQm and VTQc

VTQm, virtual touch™ quantification at margin of a lesion. VTQc, virtual touch™ quantification at center of a lesion. The figure shows the area under the curve (AUC), specificity and sensitivity of Elasticity score, VTQm and VTQc. A cut-off point of 2.50 was selected for elasticity score yielding a sensitivity of 0.872 (95%CI, 0.795 to 0.940), a specificity of 0.736 (95%CI, 0.660 to 0.805) and an area under the curve of 0.854. A cut-off point of 2.860 m/s was selected for VTQm yielding a sensitivity of 0.731 (95%CI, 0.628 to 0.821), a specificity of 0.742 (95%CI, 0.673 to 0.805) and an AUC of 0.825. Additionally, a cut-off point of 3.015 m/s was calculated for VTQc with a sensitivity of 0.731 (95%CI, 0.628 to 0.821), a specificity of 0.698 (95%CI, 0.616 to 0.761) and an AUC of 0.857.

Table 1. The distribution of benign and malignant lesions classified by microdochectomy

Diagnosis after biopsy	Number of lesions (%)
Benign	326
No pathological lesions	167 (51.2)
Fibrocystic breast disease	82(25.1)
Fibroadenoma	60 (18.4)
Atypical ductal hyperlasia	11(3.5)
Intraductal pailloma	6(1.8)
Maglinant	78
Invasive ductal carcinoma	61(78.2)
Ductal carcinoma in situ	6(7.7)
Paillary carcinoma	7(9.0)
Lobular carcinoma	4(5.1)

Measurements	Correctly positive	Correctly negative	Sensitivity (%)	Specificity (%)	PPV(%)	NPV(%)
Synthesized score (n=404)	70/78	235/326	89.7 (83.3 to 96.2)	72.1 (66.9 to 77.0)	43.5 (35.8 to 51.1)	96.7 (94.5 to 99.0)

Table 2. Predictive value of the synthesized quantitative measurement

Abbreviations: SE, systematic error. CI, confidence interval. PPV, positive predictive value. NPV, negative predictive value.

Table 3.

BI-RADS*	Elasticity score	VTQm	VTQc	Synthesized score		The BI-RADS classification and the synthesized
	Mean(sd)	Mean(sd)	Mean(sd)	Benign(n, %)	Malignant(n, %)	
3(n=293)	1.98(0.64)	2.64(0.51)	2.86(0.55)	207(85.2)	86(53.4)	classification
4A(n=46)	2.84(0.68)	2.85(0.76)	3.02(0.76)	25(10.3)	21(13.1)	and the
4B(n=23)	3.91(0.29)	3.24(0.86)	3.48(0.78)	4(1.6)	19(11.8)	synthesi
4C(n=16)	3.71(0.61)	2.90(0.70)	3.34(0.84)	5(2.1)	11(6.8)	zed
5(n=26)	4.00(0.81)	3.31(0.62)	3.71(0.75)	2(0.8)	24(14.9)	

measures

Abbreviations: BI-RADS: the Breast Imaging Reporting and Data System. VTQm, virtual touch™ quantification at margin of a lesion. VTQc, virtual touch™ quantification at center of a lesion. SD, standardized deviation. N, number of counts.

* In the BI-RADS, number 3 refers to probably benign, number 4 refers to suspicious malignancy, number 5 refers to highly suggestive of malignancy. In the 4 category, a subclassification is used: (1) 4A: low suspicious for malignancy; (2) 4B: intermediate suspicious for malignancy; (3) 4C: moderate concern, but not classic for malignancy.

STARD checklist for reporting of studies of diagnostic accuracy
(version January 2003)

Section and Topic	Item #		On page #
TITLE/ABSTRACT/ KEYWORDS	1	Identify the article as a study of diagnostic accuracy (recommend MeSH heading 'sensitivity and specificity').	1
INTRODUCTION	2	State the research questions or study aims, such as estimating diagnostic accuracy or comparing accuracy between tests or across participant groups.	5
METHODS			
<i>Participants</i>	3	The study population: The inclusion and exclusion criteria, setting and locations where data were collected.	5
	4	Participant recruitment: Was recruitment based on presenting symptoms, results from previous tests, or the fact that the participants had received the index tests or the reference standard?	5
	5	Participant sampling: Was the study population a consecutive series of participants defined by the selection criteria in item 3 and 4? If not, specify how participants were further selected.	Yes
	6	Data collection: Was data collection planned before the index test and reference standard were performed (prospective study) or after (retrospective study)?	5
<i>Test methods</i>	7	The reference standard and its rationale.	5
	8	Technical specifications of material and methods involved including how and when measurements were taken, and/or cite references for index tests and reference standard.	5-8
	9	Definition of and rationale for the units, cut-offs and/or categories of the results of the index tests and the reference standard.	5-8
	10	The number, training and expertise of the persons executing and reading the index tests and the reference standard.	6, 8
	11	Whether or not the readers of the index tests and reference standard were blind (masked) to the results of the other test and describe any other clinical information available to the readers.	6, 8
<i>Statistical methods</i>	12	Methods for calculating or comparing measures of diagnostic accuracy, and the statistical methods used to quantify uncertainty (e.g. 95% confidence intervals).	9-10
	13	Methods for calculating test reproducibility, if done.	9
RESULTS			
<i>Participants</i>	14	When study was performed, including beginning and end dates of recruitment.	10
	15	Clinical and demographic characteristics of the study population (at least information on age, gender, spectrum of presenting symptoms).	10
	16	The number of participants satisfying the criteria for inclusion who did or did not undergo the index tests and/or the reference standard; describe why participants failed to undergo either test (a flow diagram is strongly recommended).	10, figure 1
<i>Test results</i>	17	Time-interval between the index tests and the reference standard, and any treatment administered in between.	10
	18	Distribution of severity of disease (define criteria) in those with the target condition; other diagnoses in participants without the target condition.	10
	19	A cross tabulation of the results of the index tests (including indeterminate and missing results) by the results of the reference standard; for continuous results, the distribution of the test results by the results of the reference standard.	10, table 2
	20	Any adverse events from performing the index tests or the reference standard.	10
<i>Estimates</i>	21	Estimates of diagnostic accuracy and measures of statistical uncertainty (e.g. 95% confidence intervals).	11-12, table 2
	22	How indeterminate results, missing data and outliers of the index tests were handled.	7, 11-12
	23	Estimates of variability of diagnostic accuracy between subgroups of participants, readers or centers, if done.	No
	24	Estimates of test reproducibility, if done.	No
DISCUSSION	25	Discuss the clinical applicability of the study findings.	12-13
